# THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

## VOLUME XII.

FROM NOVEMBER 17, 1883, TO MAY 10, 1884.

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.

LONDON:

Printed and Published for the Proprietors by GEORGE TUCKER, at "THE ELECTRICIAN" Offices, 1, Salisbury-court, Fleet-street, E.C.

1884.

v.12

# INDEX TO VOL. XII.

51282

## A

Accumulators (*see* BATTERIES, Secondary).
Adams, Prof. W. G., Address as President of Soc. of Telegraph Engineers, 234, 478, 501, 526, 546, 567, 595.
Alloys, E.M.F. of, by J. Trowbridge and E. K. Stevens, 89.
Ammeter made by Consolidated Electric Company, 395.
Amos and Appold's Dynamometer, 104.
Ampère's Telegraph, 259.
Anglo-American Brush Company (Leading Article), 324.
Auroræ, Magnetic Storms and Sun Spots, by G. W. von Tunzelmann, 425, 450.
Ayrton and Perry's Dynamometer, 104, 345.
Ayrton and Perry's, Profs., Direct-reading Electric Measuring Instruments, 347, 370.

## B

Ballistic Galvanometer, The, 344.
Bandsept, A., Construction of Accumulators, 85.
Batteries, Primary :—
  E.M.F. of a Daniell Cell, by Prof. Exner, 14.
  for Electric Lighting, 61, 248, 349.
  Ross's, 133.
Batteries, Secondary :—
  Construction of, by A. Bandsept, 85.
  by Prof. O. Lodge, 15, 43.
  Progress in During 1883, 181.
  Report on the Brush, by Prof. Cross, 294.
Belts, How to Calculate Width of, by E. Krause, 153.
Bicycle Bell, Volk's, 318.
Bidwell, S., Hall's Phenomenon, 427.
Books, Reviews of (*see* REVIEWS).
Bright, E., Electric Fire Alarms, 296.
Brighton, Electric Railway at, 394.
British Association Meeting at Montreal (Leading Article), 468.
Brown's Dynamometer, 538.
Brunton and Wilder's Carbon Testing Apparatus, 159.
Brush Electric Light Company, The (Leading Article), 324.
Brush Secondary Battery, Report on, by Prof. Cross, 294.

## C

Cable Hauling Gear, Johnson and Phillips', 40.
Cable Work in 1883, 204.
Cables and Surveys (Leading Article), 132.
Cables, Decay and Renewal of, by Trott and Hamilton, 92.
Cables, Deep Sea (Leading Article), 84.
Cables, Spanish National, Soundings taken for, 115.
Carbons, Apparatus for Testing, 159.
Carpentier's Dynamometer, 79.
Central News Company *v.* Eastern Telegraph Company, *et aliis*, 407, 613.
Clausius, Prof., Theory of Dynamos, 175, 230, 247, 301, 397, 469, 487, 520.
Clutch, Mather and Platt's, 417.

COMPANIES' MEETINGS, REPORTS, &C :—
  Anglo-American Brush, 286, 310, 381.
  Anglo-American Telegraph, 285, 330.
COMPANIES' MEETINGS (*continued*) :
  Australasian Electric Light, 238, 503.
  Birmingham and Warwickshire Brush, 24, 119.
  Brazilian Submarine Telegraph, 552, 571.
  British Insulite, 307, 453.
  Brush Electric Light of Scotland, 599.
  Brush Midland, 71.
  Cuba Submarine Telegraph, 312, 332.
  Direct Spanish Telegraph, 479.
  Direct United States Cable, 283, 327.
  Dundee and District Telephonic Company, General Meeting, 315.
  Eastern Electric Light, 120, 141, 406, 528, 575.
  Eastern Extension Telegraph, 46, 570.
  Eastern Telegraph, 261, 284.
  Electric Sun Lamp, 263.
  Electrical Power Storage, 551, 572, 624.
  Faure Accumulator, 96, 528, 551.
  German Union Telegraph, 480, 502.
  Great Northern Telegraph, of Copenhagen, 530, 623.
  Gülcher Electric Light, 382, 455.
  Hammond Electric Light and Power Supply, 22, 72, 528, 549, 623.
  India Rubber, Gutta Percha, &c., 360, 380, 431.
  Indian and Oriental Electric Storage, &c., 166, 192, 239.
  Indo-European Telegraph, 597.
  International Electric, 168, 190.
  Jablochkoff Electric Light, 309.
  Lancashire Maxim-Weston, 431.
  London Platino-Brazilian Telegraph, 189.
  Maxim-Weston Electric, 624.
  Mediterranean Extension Telegraph, 214.
  Metropolitan Brush, 143, 332, 381.
  Monte Vedean and Brazilian Telegraph, 571.
  National Telephone, 360.
  Oriental Telephone Company, 598.
  Pilsen-Joel, 406.
  Provincial Brush Electric Light, 70, 598.
  Railway and Electric Appliance, 573.
  Reuter's Telegram, 571.
  South African Brush, 67, 215, 308.
  South Eastern Brush, 69, 454, 504.
  Submarine Cables Trust, 599.
  Submarine Telegraph, 283, 311.
  Swan United, 118, 286, 359.
  Telegraph Construction and Maintenance, 360, 379.
  Telephone Company of Ireland, 576.
  United Telephone, 262, 336.
  West Coast of America Telegraph, 240.
  Western and Brazilian Telegraph, 240, 261.
  Yorkshire Brush, 120.

Conductors and Currents, Proportion Between, by Professor G. Forbes, 500.
Conductors, Electrical, by W. H. Preece, 94.
Conductors, Method of Calculating Horse-power Expended in, by J. E. H. Gordon, 137.
Conductors, Table of, by W. Geipel, 522.
Consolidated Electric Company's Ammeter, Cut-out, &c., 395.

CORRESPONDENCE :—
  Accumulators (*see* BATTERIES, Secondary).
  Amperian Current Hypothesis, 214, 231, 253, 275, 304, 319, 351, 373, 399, 445.
  Anderson and Munro, Overhead Wires, 377.
  Anthony, W. A., Comparing E.M.F. of Batteries, 155.
CORRESPONDENCE (*continued*) :
  Anglo-American Brush Corporation, 256.
  Appold's Brake, 139.
  Armatures, Causes of Heating in Cores of, 470, 542.
  Arnot, M. N., Electrical Conductors, 565, 590.
  Axial Motion of the Earth, 518.
  Ayrton and Perry's Dynamometer, 155.
  Ayrton and Perry's Formulæ, 305, 323, 354, 376, 402.
  "B" for an "S," A, 611.
  Batteries, Primary :—
    Comparing E.M.F. of, 155.
    Consumption of Zinc in, 110, 275.
    for Electric Lighting, 81, 110, 275, 305, 352, 375.
    Finding Internal Resistance of, 470, 495.
    Lalande-Chaperon and Bennett, 253.
    Modifying Resistance of, 352, 376.
    Sauer's Photo-electric, 213.
  Batteries, Secondary :—
    A New, 352.
    Elwell-Parker, 214, 232, 255, 275.
  Bengough, A. H., What is Electricity? 109.
  Bottomley, J. T., Heating Effects of Electric Currents, 541, 590.
  Bowen, W. F., The Band in the Siemens Dynamo, 543.
  Brackett, Prof. C. F., New Energy Meter, 82.
  Brackett's Energy Meter, 82, 402.
  Bright, Sir C. T., and the Gaulard-Gibbs System, 353, 378.
  Bryan, J. W., The Maxim-Weston Company in England, 590.
  Carbon, Peculiar Action of, 323.
  Carriages, Lighting of, 11.
  Characteristic Curves of Dynamos, 517.
  Chloride of Silver Battery, 39.
  Church, A. H., Primary Batteries, 81.
  Cottrell, W. H., Recent Sunrises and Sunsets, 446.
  Crompton, R. E., Efficiency of Dynamos, 517.
  Current, Distribution of, in Networks of Conductors for Incandescent Lighting, 353.
  Currents, Heating Effects of, 541.
  Cuttriss, C., Peculiar Action of Carbon, 323.
  Davy MSS., The, 257.
  De Vane, J., Magneto Electric Induction, 109.
  Dobson, S. T., Resistance Expressed as a Velocity, 376, 448.
  Dorman, C. M., Amperian Current Hypothesis, 445.
  D'Or's Lamp, 39.
  Dublin, Electric Lighting in, 543.
  Duncan, J. B., Charging the Swan Lamp, 141.
  Dunston, R. E., Efficiency of Dynamos, 446.
  Dynamo, Defective, 11, 39, 63, 81, 111, 140, 154, 187, 213, 233.
  Dynamo, a Small, 187, 233.
  Dynamos :—
    Amperian Currents in (*see* AMPERIAN CURRENTS).
    Causes of Heating in Armature Cores, 470, 542.
    Characteristic Curves of, 517.
    Defective, 11, 39, 63, 81.
    Efficiency of, 446, 517.
    Endless Chain, 38, 61, 110, 140.
    Physical Theory of, 446.
    Running Two Together, 233, 257, 275.
    Small, 565, 591.
    The Band in Siemens', 543

Digitized by Google

CORRESPONDENCE (*continued*):
Dynamos :—
Theory of Elphinstone-Vincent, 402.
Theory of the Gramme, 213, 303, 306, 319, 351, 373, 399, 421, 423, 448.
Dynamometers, Mechanical, 139. 140. 155, 187.
Earth, Axial Motion of, 518.
Earth Currents, 493.
Earthquakes, 63, 111.
Electric Conductors, 565, 610.
Electric Lamp, D'Or's, 39.
Electric Light in Foreign Railway Stations, 542.
Electric Light for Railway Carriages, 472, 542.
Electric Lighting at Gaiety Theatre, Glasgow, 111.
Electric Lighting in Dublin, 543.
Electric Sun Lamp Company, 257.
Electricity, What is it? 109, 140, 187.
Electrolysis, Separating Metals by, 11.
Elphinstone-Vincent Dynamo, Theory of, 402.
Elwell-Parker Secondary Battery, 214, 232, 255, 275.
Energy Meter, Brachett's, 82, 402.
Ermacora, G. B., Endless Chain Dynamos, 38, 110.
Fahie, J. A., Electric Lighting in Dublin, 543.
Fahie, J. J., the Davy MSS., 257.
Farquhar, W. T., Defective Dynamo, 39, 81, 140.
Farrar, W., Gravet's Rule, 39, 64.
FitzGerald, D. G. :—
Amperian Current Hypothesis, 231, 275, 399.
Magneto-Electric Induction, 141.
Primary Batteries for Electric Lighting, 305.
Secondary Batteries, 232.
Theory of Gramme Dynamo, 213, 319, 373, 399, 421, 448.
What is Electricity? 140.
Fletcher, J. W., Watchmen's Detectors, 355, 404, 423.
Forbes, George, The Heating Effects of Electric Currents, 563.
Force, Lines of, Theory (*see* DYNAMOS).

RELEASED BY THE UNIVERSITY OF CALIFORNIA

# THE ELECTRICIAN:

A WEEKLY JOURNAL OF

THEORETICAL AND APPLIED ELECTRICITY AND CHEMICAL PHYSICS.

No. 1.—Vol. XII. SATURDAY, NOVEMBER 17, 1883. Price 4d.

## NOTES.

Australian Tariffs.—The tariff between New South Wales and Tasmania has been reduced to 3s. for ten words, and 3d. for each additional word.

The Brush System in the City.—Owing, it is stated, to some defect in the cable, the whole of the Brush lamps in the City went out on Monday week soon after 5 p.m., and were not got properly to work until the following evening.

Death of a Telegraph Superintendent.—The death is announced of Mr. C. J. Murphy, assistant superintendent in the service of the Central and South American Telegraph Company. The date of his death is given as October 3.

Lighting Tenders Wanted.—The Town Council of Winchester are inviting tenders for lighting the city. Particulars can be obtained of Mr. Walter Bailey, Town Clerk. Sealed tenders, marked "Lighting," are to be sent in to him by the 24th inst.

A Horizontal Electromotor.—A horizontal electromotor with piston movement is being exhibited at Freeman and Daly's, New York. Its inventor claims wonderful things for it, but we fail to see how it can compete with ordinary rotary motors.

Illness of Mr. Patey.—Mr. Patey, the secretary of the Telegraph Department, who has been seriously ill in Paris, is now, we are glad to hear, in a fair way for recovery, although not expected to resume his official duties for some weeks to come. Mr. Patey was attacked with inflammation of the lungs while on a visit to Paris.

Electric Lighting for Lighthouses.—Operations have been commenced at the South Foreland, says a contemporary, towards erecting three temporary lighthouses for the purpose of testing the respective values of gas, paraffin oil, and the electric light applied on a new principle, as lighthouse illuminants, with the view to adopting the best.

Aurora.—On Friday evening, November 9, an aurora was seen by independent observers at Sevenoaks, in Kent, and Freshwater, Isle of Wight. It is described as having a crimson glow and resembling "the tremulous red glare" of a London fire when viewed from a distance. It does not appear to have lasted much longer than an hour.

The Royal Society.—The Council of the Royal Society have awarded the Copley Medal to Professor Sir William Thomson, F.R.S., for (1) his discovery of the law of the universal dissipation of energy; (2) his researches and eminent services in physics, both experimental and mathematical, especially in the theory of electricity and thermo-dynamics.

Overhead Wires in America.—A man has just obtained a verdict for 6,000 dollars damages against the Western Union Telegraph Company because in crossing a railway at night on a mule he was caught by the wires, which had sagged nearly to the ground, and thrown from his seat. We are glad to say that we never saw wires in this country sag to such an extent as this.

Electric Lighting for Hotels.—The Edison and Swan United Electric Light Company are going to light the Great Hall and Pillar Hall in Cannon-street Hotel, which belongs to the South Eastern Railway Company. Two hundred incandescent lamps will be used. The current will be supplied by an Edison K dynamo, which will be driven by an engine supplied by Marshall and Son, of Gainsborough.

Society of Telegraph Engineers.—The next meeting of this society will be held at the Institution of Civil Engineers, at 8 p.m., on Thursday, November 22nd, when the following papers will be read: "Submarine Telegraph Cables, their Decay and Renewal," by S. Trott and F. A. Hamilton, associates; "Trott and Kingsford's Automatic Grapnel for Submarine Cables and Torpedo Lines," by H. Kingsford, associate.

The New Law Courts Chambers.—These chambers, which front the Courts of Justice in the Strand, have at last been finished. In addition to chambers, there is an hotel and restaurant in the same building. The lighting is on the incandescent system, and has been carried out by Messrs. R. E. Crompton and Co., engineers to the Swan United Electric Light Company. Swan lamps are used, and they appear to give a very steady and good light. The dynamos are driven by a Marshall engine.

Electric Lighting in New York.—According to an American contemporary a contract for lighting the new building of the Mutual Life Insurance Company in Nassau-street, New York, has been awarded to the Sawyer-Mann Illuminating Company, which is the licensee in that city of the Consolidated Electric Light Company. The plant will consist of 1,500 standard 16-candle lamps and 10 Sawyer lamps of 125 candle-power each, the latter to be used for lighting large indoor spaces. The steam power will be obtained from the pipes of the New York Steam Company.

A Novel Lightning Arrester.—The *Operator* says that an American railway telegraphist, being in want of a lightning arrester, and not having one, tried the following, which answered well. He took the loose ends of the ground wire and hooked it around the covered main line. He appears to have had some doubt as to whether the succession of discharges would not eventually have burnt the insulation, but asks, "would not a sort of metal covering, say an inch long, placed around the cotton insulation of the main line, and then attached to the ground wire, be as good as anything, if not better? It seems to work perfectly."

Arrangement of Secondary Cells.—It has been asked why something has not been done with the form of regulator battery for compound parallel incandescent work, that was

Digitized by Google

shown by Mr. Henry Edmunds, in conjunction with the Swan lighting, at the Paris Electric Light Exhibition in 1881, and which enabled him to show the jurors how he could turn out any number of lamps in parallel from maximum to zero without affecting the other lamps in the neighbouring series in any way. His device was simply a number of lead pyramidal cones, very easily formed, without seam or joint, out of sheet lead, separated by pieces of wood, and placed one above the other. Each inverted cone-shaped tray was filled with acidulated water, and the terminals were simply attached to the top and bottom tray, or inverted pyramidal cone element.

Electric Light in Dyeworks.—In winter months matching colours in cloth and paper with artificial light becomes difficult, and almost impossible. Messrs. Deakin, of Belmont, have therefore adapted the Swan incandescent light in their works, and it has proved all that could be desired. The lamps are used at their full power (20 c.-p.), and it is now possible to work as long as required. The full number of lamps in use is 75, the current being supplied by two Lumley dynamos. Safety plugs to melt with 20 per cent. extra current are used in every circuit. The power is supplied by the engine in use at the works, and as it is compelled to go at one uniform speed resistances are inserted, and can be switched on in place of any number of lamps that may not be wanted. The installation has been carried out by Mr. W. Banks, of Bolton.

The Edison System in the Strand.—After extensive alterations and redecoration, Messrs. Gatti's Adelaide Restaurant, Strand, is now lighted by means of about 330 incandescent lamps. A special feature in connection with the lighting is the duplication of the generating plant. There are two Field boilers, two Armington engines, and four Edison dynamos. The steam piping is so arranged that either engine can be run from either boiler and the shafting, so that any two of the dynamos can be driven by either engine. If one boiler should fail the other would supply sufficient steam to drive one engine. If one engine stopped the other would still run two dynamos, which in turn could sustain the entire number of lamps. The most careful provision has thus been made to guard against the possibility of a break in the lighting through any accident to the machinery.

The Telephone in London.—On the 15th October last the number of subscribers to the United Telephone Company's system was 3,081, and the number of calls on that day 21,371. Allowing a minimum of two messages to each call, this gives us 42,742 as the number of messages sent on that date, or an average of 13·87 per subscriber. From figures prepared by Mr. J. W. Batten, it would appear that the cost of each message, exclusive of Government duty, was ·86d. On the 20th of the same month the number of subscribers had risen to 3,090, but the number of calls was only 14,583 (owing to the 20th being a Saturday). This gives us 29,166 messages, or an average of 9·43 per subscriber. The cost of each message was, according to Mr. Batten, 1·27d. It is upon these figures that Mr. Batten bases his appeal for penny messages, which will be found in another "Note."

Death of Dr. Gale.—Dr. Leonard D. Gale, an old well-known scientist, died in Washington on Tuesday, the 23rd ult., at the age of eighty-three. He was at one time (says the *Electrical World*) associated with Professor Morse in the University of the City of New York, and is said to have brought to the knowledge of the latter in 1834 the discoveries in electricity of Professor Henry, the application of which by Professor Morse to his machine contributed largely to its success. He assisted Professor Morse in building the first telegraph line between Washington and Baltimore. He went to Washington in 1846, having been appointed an examiner of patents, and has since resided there. Until 1857 he had charge of the department of chemistry in the U.S. Patent Office. In that year he was removed for political reasons, and for many years afterwards practised as a patent attorney.

Ship Lighting.—On Monday last the ss. "Tamalipus," which has just been built and engined by Messrs. R. Napier and Sons, of Govan, on the Clyde, for the Compania Mexicana Transatlantica, went for her official speed trial trip. She is a splendid vessel, her general dimensions being:—Length between perpendiculars, 400ft.; breadth (extreme), 44ft.; depth (moulded), 32ft. 6in.; with a gross tonnage of 4,150 tons. The machinery consists of a set of three cylinder triple expansion engines (Napier's patent), which indicate 5,000 horse-power, and steam is supplied by four double-ended steel boilers for a working pressure of 140lb. She is most handsomely furnished, and is also fitted up throughout with Swan incandescent lamps, Siemens machines being used to generate the current. The work has been carried out by Mr. Miller, of Glasgow, under the supervision of Mr. Andrew Jamieson, C.E.

The Lord Mayor's Show and the Telephone.—A correspondent of the *Globe*, writing on the 9th inst., says:—"I was in an office at Islington at about a quarter to one to-day, where there is a telephone communicating with a basement in Cheapside. A gentleman at Cheapside kindly told me the show was about to pass, and left the instrument open for me to listen. I heard a crescendo and diminuendo murmur, but it was sometimes difficult to say which sounds were due to induction and which to drums. At times a rhythmical bumping was very evident, but I did not catch a note of music. I think a certain rushy squeaky sound in the early part of the procession must have been bagpipes, but it may have been only fifes. At last came a great crescendo sputtering or buzzing, like a frying-pan, and, after a pause, a smooth rushing sound. I afterwards heard that the late Lord Mayor was loudly cheered and the new one hissed at this spot."

Magnetic Disturbances.—Mr. William Ellis, of the Royal Observatory, Greenwich, writes to the editor of the *Colliery Guardian* as follows:—"By request of the Astronomer Royal, and in continuation of previous notices, I send herewith further information in regard to magnetic disturbances, as observed at the Royal Observatory. The needle was disturbed from 5 h. p.m. on April 24 until 2 h. a.m. on April 25, variations of 30 minutes being observed; again, from 7 h. p.m. on May 20 until 5 h. a.m. on May 21, variations of 20 minutes being recorded. The needle was also somewhat disturbed on the evening and night of May 21, on the evening and night of June 30, and on the night of July 1 there was some disturbance, and between 11 h. p.m. on July 11 and 6 h. a.m. on July 12 there were variations of 30 minutes. From 11 h. p.m. on July 29 to 8 h. a.m. on August 2 frequent fluctuations of from 10 to 15 minutes were observed. Between 6 h. p.m. on August 18 and 4 h. a.m. on August 19 variations of 20 minutes, and between 2 h. a.m. on September 16 and 9 h. a.m. on September 17 variations of 45 minutes were observed. From 4 h. p.m. to 7 h p.m. on October 5 there were variations of 40 minutes, and between 6 h. p.m. on October 16 and 6 h. a.m. on October 17 variations of 30 minutes observed. The needle was again somewhat disturbed on the evening of October 20."

A Penny Telephone Message.—Mr. J. W. Batten writes

Digitized by Google

to *The Times* in favour of penny messages by telephone. He says:—"I have a firm belief that it is not only possible, but that it would become profitable, and if the Government would assist by taking the tax off all penny messages just as they have taken the passenger duty off all railway fares at a penny per mile, we would, at any rate, try the experiment, and open, say, 100 offices in different parts of London. That the use of the telephone in no way interferes with the Government telegraphs is obvious from the postal returns. The daily postal telegrams in the London area, which in 1881 were 30,620, rose in 1883 to 33,996, while in the same period the telephonic messages rose from *nil* to 41,261. The London postal area has 453 square miles, as compared with the 79 square miles the limit of the Telephone Company's license. Of course, with the penny message will come the demand for an extension of this area, and inasmuch as a telephone will convey a message as easily ten miles as one, I would suggest that the area be extended to the limits of the London postal area. It will indeed be a great boon to persons residing in the suburbs of London if they are enabled at the cost of a penny to converse with their clerks or servants in the City without the necessity of the journey on a wet or foggy day. The sixpenny telegram, with its reply arriving two or three hours after, hardly meets the wants of the age. What we all want is just that which the telephone permits, the instantaneous reply to the question asked."

Quick Work.—Two installations of incandescent lighting have recently been put up by Messrs. Laing, Wharton, and Down, of Holborn-viaduct, in remarkably short time. The first was at the late Brewers' Exhibition at the Agricultural Hall, when Messrs. Laing, Wharton, and Down were applied to on the Monday morning to light up two of the exhibition stalls that evening. A dynamo, wire, lamps, &c., were at once sent up to the hall. Messrs. Hindley provided the power, and by 9:30 that evening the installation, consisting of thirty-two lamps, was at work, and ran during the whole of the exhibition, lasting a week. The machine used was a B Bürgin, with fifty volt lamps, arranged two in series. The other instance was at Kendal, where Messrs. Laing, Wharton, and Down received the order on Tuesday evening to light up a local exhibition which was to open on the Thursday. Mr. Wharton happened to be in the neighbourhood with some workmen fitting up the Gunpowder Works of Messrs. Wakefield at Gatebeck, and at once wired to London for dynamo, wire, lamps, &c., which arrived at Kendal on the Wednesday evening, and by Thursday midday all was ready to run, three rooms being lighted with about thirty 20 candle-power lamps from a compound-wound 30-light Gramme. The power was obtained from a portable engine lent by Messrs. G. Gilkes and Co. (late Williamson Brothers), the well-known turbine makers. The installation worked without a hitch, and greatly astonished and delighted the inhabitants of Kendal, to whom this was the first exhibition of incandescent lighting.

A Compromise in Dublin.—We learn that the Dublin Gas Company is engaged in introducing the electric light in Dublin, having recently purchased the plant of the late Dublin Brush Electric Light Company. It will be interesting to note whether electric lighting will make more favourable progress in future in the sister isle now that this powerful and influential local company has withdrawn its opposition to the system, and actually gone in for the business itself. We remember that recently the secretary of the company, when seeking further parliamentary powers, declared before a committee of the House of Lords that he did not believe in electric lighting, and that his company did not want to touch it. It appears now, however, that he has quite altered his opinion, and that his company are going actively into the new enterprise. And, moreover, it appears that they have commenced supplying the electric light without seeking the necessary permission either from the local authority or the Board of Trade, in accordance with the provisions of the Electric Light Act of last year, the company relying on an Act of 1866 which empowers them to manufacture and supply gas and other improved means of lighting, maintaining that the words "other improved means of lighting," extend to and cover any or every method of artificial illumination then or hereafter to be discovered. To this interpretation exception is being taken; and we are informed that notice has been given in the Town Council to the effect that legal proceedings will be instituted to restrain the gas company from laying down wires for the purpose of lighting by electricity without the formal authority as conferred under the Electric Light Act.

Electric Lighting in Paris.—The Paris correspondent of the *Daily Telegraph* states in last Tuesday's issue of that paper that "electric lighting is again coming to the fore in Paris. The Director of the Postal and Telegraphic Department, M. Cochéry, has just had 1,200 lamps put up in the general office in the Place du Carousel. The lamps are supplied by the Faure accumulators, and the steady even light obtained by this means has decided the enterprising Postmaster-General to give the system the comparatively long trial of eighteen months. The Continental Hotel was also lighted up for the first time last night by the same system, the electricity being brought to one of the doors of the hotel stored in a cart. Communication with the candelabra in the largest room of the first floor was established in a few moments, in the presence of some 300 visitors. Many of those present afterwards journeyed to the Arc de Triomphe and back in a tramcar propelled by electricity supplied in the selfsame accummulators, by way of testing the availability of the power thus stored. I hear from Berlin that a contract was signed there yesterday by virtue of which the Edison Company has purchased for the whole of Germany the right of using the Faure-Sellon-Volckmar accumulators, the arrangement being made through the instrumentality of Messrs. Landauer and Sulzbach. I hear also that the Electrical Power Storage Company is to receive before the end of the year £30,000 for its rights, and that £10,000 have already been paid in cash." The information as to the German Edison Company, and the Faure-Sellon-Volckmar accumulators, should we think be accepted with all reserve, at all events for the present.

Overhead Wires.—The St. Olave's District Board of Works are puzzling their heads as to what they shall do with the telephone wires which have invaded their district. One was about to be run across St. John's churchyard in their district, without the Board's leave, upon which the clerk directed the lineman to stop further operations, which he did. On the following morning, however, the clerk found that the man had climbed the churchyard railings and that the wire had been fixed. A letter to the secretary of the Telephone Company concerned brought explanations, &c., and a statement that the man had been reprimanded. The above fact were communicated to the Board by their clerk at its last meeting. At the same time their surveyor reported that early last week, on Tuesday, eight wires, the property of the United Telephone Company, fell into the roadway between the poles fixed upon the Old King's Head public house at the corner of Stoney-lane and Tooley-street and the Central Bank

Digitized by Google

Tooley-street. This accident arose from the men engaged in removing the wires from the pole of the Old King's Head having fastened six of the wires round a small stack of chimneys consisting of three flues built up above the parapet wall on the west side of the public house, which gave way from the strain or weight of the wires around it, throwing the brickwork on to the vacant land below, fortunately without injury to any person in the street. There was, however, one man driving a van in Tooley-street, towards Duke-street, who very narrowly escaped being caught by the wires as they fell. The wires have since been reinstated, and with additional wires to the number of 10. The chimneys have also been rebuilt. Telephone companies will have to look after their *employés* sharply and soon, or the public will want to know why they should be exposed to such risks as these.

New Method of Insulating Wires.—In the *Comptes Rendus* of the 15th of October, M. Wiedemann gives an account of a new method of insulating metallic conductors. Having had occasion to employ the methods of Nobili and Becquerel in the decoration of objects of art, he observed that the parts so coloured became absolute non-conductors of the galvanic current when the process was completed of covering their surfaces in this way with peroxide of lead or of iron. A wire of copper or brass, or even of iron, can in this way be coated with an insulating surface, and the inventor thinks that in telegraphy and telephony an application of this process may be very useful. The process is simple, and the cost small, and the power of the insulating surface to withstand the effects of atmospheric action is a guarantee of its durability. The insulation is, moreover, absolute. The following is the process: Prepare a bath of plombate of potash by dissolving 10 grams of litharge in a litre of water, to which 200 grams of caustic potash is added, and boil the mixture for about half an hour. Allow the liquor to stand, then decant and the bath is ready for use. Fix to the positive wire the metal wire destined to receive the peroxide of lead, and place in the bath a small anode of platinum attached to the negative wire. Highly divided particles of lead will precipitate themselves on the negative pole, while peroxide of lead forms on the metallic wire, which passes successively through all the colours of the spectrum. The insulation is not perfect until the wire reaches its last tint, which is a black brown. The wire so covered is perfectly insensible to electric current. Small clean objects attached to the surface can be brought to the negative pole of a gilding, silvering, or nickelling bath without any deposit taking place upon them. Such a wire placed in the current and brought into contact with another wire in connection with a galvanometer leaves this perfectly unmoved. There is no deviation at all from the current flowing through the wire. M. Wiedemann thinks that such a method will be highly advantageous in the construction of galvanometer coils and other instruments.

The Edison System in New York.—On the 23rd of last month a breakdown occurred with the Edison system in New York. It appears from the New York papers that 4,700 lamps, fed from the Pearl-street station of the Edison Company, went out suddenly at 5:15 p.m. on the above date. The company's explanation of the breakdown is that the evening in question being dark and rainy, nearly all the lights were wanted early in the evening, and at the same time. The consequence was that more current was sent into the mains than had ever before been the case; in fact, they were overloaded. A very natural, and, in fact, proper result of this overloading was the fusing of the safety plugs, with which, as our readers know, the Edison system of circuits is well provided. Had these plugs not been provided, or had they failed to act, fire might have resulted somewhere. As it is a few plugs have gone, which are readily replaced, and the Edison Company have learnt a lesson. There has evidently been a miscalculation as to the carrying power of their leads, an error which is readily remediable. In fact, we see from the papers before us that Mr. Eaton, the vice-president of the company, states that "hereafter larger leads will be used, so that a similar accident may not occur again." It is a pity the breakdown has occurred, but we cannot help thinking, nevertheless, that it affords an apt and striking illustration of the efficiency of the Edison system, paradoxical as this statement may seem from one point of view. The safety plugs, an important part of the Edison system, acted promptly and exactly in the way they were intended to act. When fused there was no difficulty in getting at them to put new ones into the circuit, because they were fitted in iron boxes, access to which is obtained by simply lifting a lid. The time, therefore, required to put new plugs in, and have the lamps burning again was reduced to a minimum. As we have said the Edison Company have evidently made a miscalculation, which will be rectified in the future, and we may hope that there will be no more breakdowns. We may point out that this installation has been running without a hitch for a year or more, and we think this fact should be borne in mind in estimating the above breakdown.

The Transmission of Energy.—It is well known that the town of Geneva is about to erect large works on the banks of the Rhone, the waters of which they intend to utilise for distributing and supplying motive power throughout the town. Before finally settling the method of utilising the water power, they appointed a committee to consider the matter. This committee was composed of MM. Legler, Achard, Pictet, and Turrettini. These gentlemen drew up a report in which they considered the various methods that might be adopted, and, amongst others, that based on the generation and distribution of electrical energy. One great obstacle to this method was, however, in their opinion, the loss that occurs in the distribution of electricity. "This loss," the report says, "is due to three prime causes; the heating produced by the resistance of the generator, the heating produced by the resistance of the cable, and the heating produced by the resistance of the receiver. These three factors, to which must be added the relatively small amount of friction in the two machines, are the principal cause of the loss of power, which must not be overlooked, for in the celebrated experiments of M. Marcel Deprez at Munich, and at the Gare du Nord, at Paris, they amounted together to about 70 per cent., thus leaving a useful return of 30 per cent. only. It is but just to mention that M. Deprez had been pleased to exaggerate the difficulties in his experiments by employing iron cables and by trying to generate a difference of potential of several thousand volts in one machine alone, which rendered it very delicate, and reduced to a great extent the power obtained, owing to the insufficiency of the insulation of the wires of his machine in the presence of such colossal differences of potential. The distance to which M. Deprez transmitted energy was 8·5 kilometers. It is unlikely that in Geneva we should have to transmit so far from the generating station, therefore the problem is to a certain extent simplified." The report further considers that it would not be good to have a higher electromotive force than 500 volts, in view of possible accidents to persons. For the present, therefore, there does not appear to be any chance of Geneva utilising its water power to generate electricity and distri-

Digitized by Google

buting the latter. The report is in favour of the adoption of a system of transmitting water under pressure, to be utilised as required.

THE ELECTRIC LIGHT AT THE FISHERIES EXHIBITION.—On Saturday evening last a dinner was given at the invitation of the executive committee to the exhibitors of the electric light apparatus, and the members of the scientific press. The *raison d'etre* of the dinner was to allow the heartiest thanks of the committee to be given to the electric light exhibitors who had exhibited gratuitously—and at the cost, probably, of some £20,000—for the aid which had thus been given. It was admitted by speaker after speaker that the success of the exhibition was due in a great measure to the electric light. We agree with this opinion, although one of our colleagues on the scientific press thought the same success would have been achieved had gas been the illuminant. While, however, holding the general opinion to be correct, we may take this opportunity of saying what has long been in our minds. The exhibitors of the electric light have contributed their quota to the general pleasure. Not only have they exhibited at the Fisheries, but they have exhibited here, there, and everywhere. Now there must be an end of this system of gratuitous exhibition. The promoters of exhibitions may think it pays the exhibitors as an advertisement; the shareholders of the companies know better, and the managers of the companies who seem to possess most foresight are beginning to hold aloof from exhibitions. Now, if the electric light is a valuable adjunct to exhibitions, let it be paid for. It is not fair to the shareholders of companies that they should be called upon time after time to provide funds to carry out installations which are not likely to give adequate return in money or prestige. It may be an unusual proceeding on our part to partake of hospitality and to criticise the hosts. If our words are taken to imply hostile criticism as regards the Fisheries Exhibition they will be misconstrued. We take no objection to the gratuitous exhibition of the electric light at the Fisheries, but other exhibitions are to be held, and the promoters of these exhibitions should arrange to pay for the light they require. Exhibitions are not going to be continued with a purely philanthropic object in view. There are mouths to be fed and pockets to be filled, and from the point of view of the shareholders in electric light companies, we hold that they should no longer be looked upon as sheep willing to be fleeced for the benefit of other individuals. We have a strong suspicion from the tone of some of the speeches on Saturday that the promoters of the next exhibition will be glad to have the co-operation of electric light exhibitors. If the latter are prepared to accede to these constant calls, well and good, but in the present state of electric lighting, considering the value put upon shares and the claims of the shareholders, we think managers should consider more how to obtain income than how to increase expenditure.

AN ELECTRIC SIGNAL CLOCK.—In the *Journal* of the Franklin Institute for November is given a description of an electric signal clock made by Messrs. Blodgett Bros., of Boston, U.S. The description is contained in a report of the committee of the electrical section of the above institute, to whom the clock was submitted for examination. The instrument is designed (1) to give any kind of fixed signals at any regular or irregular intervals, and especially (2) to cause the striking of warning and departure signals for railway trains or street cars, according to the time table in use. The peculiar features of the instrument are as follow: An electromagnet is connected by wires to a standard clock, which closes an electric circuit once every minute. This magnet, by means of a lever and pawl, rotates a ratchet wheel of sixty teeth one step each minute. The wheel is rigidly attached to the axis of a vertical cylinder fourteen inches high, and six inches in diameter, which revolves with it, and therefore makes a complete revolution once in an hour. The cylinder has two divisions, each of which is provided with a hole for every minute of twenty-four hours, or 1,440 holes in all, arranged in a single spiral. A toothed wheel on the axis of this cylinder gearing into another of equal size imparts its motion to a coarse-threaded screw, which raises, at a rate uniform with the movement of the cylinder, a small sleeve or follower, consisting of a short lever with two arms, the forward end of which passes very near to the surface of the cylinder. The rear end of this lever is forked, and gives a lateral movement to an elongated crank, and also, by means presently to be described, to a vertical rocking shaft, bearing at its upper end a horizontal bar, adapted alternately to engage with and release stop pins of a circuit wheel. Whenever the vertical shaft is slightly rotated, the circuit wheel (which is driven by a spring clock movement) is released, and moves on a short distance. For railroad purposes two signals are usually required for every train; a warning or preliminary signal, which precedes the other by an interval of from two to five minutes, and a final or departure signal, sounded at the exact moment when the train should start. To effect this operation short pins are inserted into the holes of the cylinder, which correspond in location to the times of all the warning and departure signals. The lower division is arranged according to the week day time table, and the upper one according to the Sunday time table. The follower passes over every hole in the cylinder once in twenty-four hours. When, in the course of its traverse, it comes in contact with the first of the two pins for any train, the end is moved away from the cylinder a short distance, and, by a small rotation of the vertical shaft, deflects the horizontal bar far enough to allow a pin to pass, and thereby set the circuit wheel of the clockwork in motion. This wheel has upon its circumference a series of projections or pins, which, when the wheel revolves, come in contact with a fixed spring. The projections and spring close an electric circuit through the signal bells a certain number of times, depending on the signal to be given. When the follower comes in contact with the pin denoting the time of the second or departure signal, the operation is repeated, except that there are a different number of projections on the circuit wheel, and so a different number of strokes upon the bells, corresponding to the distinctive character of the final signal. When the time of the next train approaches, the same movements are repeated, and so on through the entire day. At midnight the follower has completed its traverse of all the holes in the cylinder, and it is then automatically detached from the screw by a cam, and falls freely to its position opposite the first pole in the series, where it becomes again attached to the screw, and begins a new day. A second follower, also connected with the elongated crank, moves in like manner over the upper part of the cylinder; but it cannot put in motion the striking mechanism during a week day. On Sunday, however, it is rendered operative, and the lower one inoperative. The committee report that the instrument has no parts that are easily deranged, nor are its adjustments difficult to be made. The wear is very slight, and the parts are all accessible for repairs. They further recommend that Messrs. Blodgett Brothers be awarded the Scott legacy medal and premium at the disposal of the institute.

## ELECTRO-CHEMISTRY.

### Inorganic.

BY DR. G. GORE, F.R.S.

The present series of articles is intended to contain, in systematic order, the chief principles and facts of electro-chemistry, and to supply to the student of electro-plating or electro-metallurgy a scientific basis upon which to build the additional practical knowledge and experience of his trade. As the series is a purely scientific one, it will not include such technical details or particulars as will enable the practical worker to obtain perfect workshop results; these may be obtained from technical books on electro-metallurgy, combined with actual workshop experience. A scientific foundation, such as is here given, of the art of electro-metallurgy is, however, indispensable to the electro-depositor who wishes to excel in his calling, and should be studied previously to and simultaneously with practical working. It is partly in consequence of deficiency of such fundamental knowledge by the British workman (and partly to the undue pursuit of wealth by his employers) that English manufactures are gradually being transferred to foreign lands. Whilst, also, the series of articles will contain the chief facts upon which the comparatively new art of electro-chemical analysis of minerals and alloys is based, it will not supply the technical details necessary for the accurate quantitative determination of metals by electro-chemical processes; references to sources of such information will, however, be given.

The molecular weights of substances, as given at the heads of the paragraphs, are in nearly all cases those of the anhydrous ones; for those of the hydrated compounds the student is referred to books on chemistry.

**History.**—The history of electro-chemistry requires only a brief description. Ages before the discovery of voltaic electricity it was known that various metals, by being simply immersed in metallic solutions, became coated with the metal previously dissolved in the liquid. Thousands of years ago Zosimus mentioned the deposition of bright metallic copper upon iron immersed in a solution of a salt of copper. In the year 1752 Sulzer remarked, "If you join two pieces of lead and silver, so that they shall be upon the same plane, and then lay them upon the tongue, you will notice a certain taste resembling that of green vitriol, while each piece apart produces no such sensation." Paetz and Van Troostvik also, in the year 1790, decomposed water by passing electric sparks through it by means of very fine gold wires.

It was, however, the discovery by Volta, in 1799, of his electric battery which gave the first great impulse to electro-chemistry. By means of it Nicholson and Carlisle first decomposed water by means of a voltaic current from a battery on May 2nd, 1800; and soon afterwards, Dr. Henry, of Manchester, decomposed nitric and sulphuric acids, and also ammonia by similar means. During the next year Dr. Wollaston discovered that if a piece of silver in connection with a more positive metal be put into a solution of copper the silver becomes coated with copper, which coating will stand the operation of burnishing. In the year 1801 Gerboin also first noticed the movements produced in mercury during the act of electrolysis. In 1803 Hisinger and Berzelius discovered that by means of a voltaic current the elements of water and of neutral salts were transferred to the respective polar wires immersed in the liquid; and Cruickshank, about the same time, observed the electro-deposition of lead, copper, and silver upon one of the polar wires (the one connected with the zinc end of the battery) immersed in solutions of salts of those metals, and was thus led to suggest the analysis of minerals by means of the voltaic current. In 1805 Brugnatelli observed the electro-deposition of gold upon silver when the former was made the negative pole in a solution of ammoniuret of gold; he also discovered the electro-deposition of zinc.

The most striking proof, however, of the great chemical power of the electric current was the discovery on October the 6th, 1807, by Sir Humphrey Davy, of the electrolytic decomposition of potash and soda, and the liberation of their respective metals, by a current from a voltaic battery composed of 274 cells. In 1826 Nobili discovered the deposition of peroxide of lead in films of beautiful colour upon the platinum plate which conveyed a voltaic current into a solution of acetate of lead, and Ritter subsequently discovered the deposition of peroxide of silver from a solution of argentic nitrate under similar conditions. In 1834 Faraday discovered the important truth that, by the passage of an electric current through an undivided series of solutions of various metallic salts, or through those salts whilst in a state of fusion, the quantity of each salt decomposed was in direct proportion to the amount of current. Also that the quantities of the different metals dissolved or deposited were in definite proportions by weight, and that those proportions were identical with those of the ordinary chemical equivalents of those metals; and he thus established the law of definite electro-chemical action. And in 1837 Dr. Golding Bird succeeded in decomposing, by means of feeble voltaic currents, solutions of the chlorides of sodium and potassium, and depositing their respective metals into mercury.

As the subject of electro-chemistry is a very large one, it is only briefly treated in the following series of articles. The general principles and phenomena will be first explained, and then will follow an account of the action of the current upon individual substances.

**Definition of Electro-Chemical Action.**—Electro-chemical action is chemical change produced by means of an electric current, and usually consists of the decomposition of a compound liquid, the liquid being resolved into its constituent parts, in certain definite proportions by weight; it is also often attended by chemical union of a metal, in certain definite proportions by weight, with one of the elements of the liquid. It is usually limited to combinations of conducting substances only.

**Chief Conditions of Electro-Chemical Action.**—The chief conditions are that the substance must be a liquid, a compound body, a conductor of electricity, and traversed by the current. The liquids decomposable by a current are usually composed of two elementary substances, the one being a metal and the other a non-metal. Liquid alloys, or liquids composed of two non-metallic elements, are not usually decomposed. Mixtures of compounds in solution are commonly decomposed more easily than solutions of single compounds; for instance, water containing sulphuric acid is decomposed much more readily than water alone.

All the products of electrolysis are set free in an almost infinitely thin layer at the immediate surfaces of the conductors at the parts where the current enters and leaves the liquid. The electro-negative products, such as the non-metallic elements and acids, are either liberated at or combine with the conductor, by which the current enters the liquid, and the electro-positive ones, such as metals and alkalies, are liberated at or combine with the conductor by which the current leaves the liquid. The behaviour of individual combinations of metals and liquids will be subsequently described.

**Conductivity of Liquids.**—Liquids present an extremely wide range of conducting power; whilst some completely resist the passage of a current from 10,000 voltaic cells in single series, others transmit freely the current from a single element. Amongst the non-conducting ones may be included all oils, benzine, petrolene, bisulphide of carbon, the liquid chlorides of carbon, terchloride and pentachloride of phosphorus, terchloride of arsenic, pentachloride of antimony, tetrachloride of tin, zinc-ethyl, perfectly pure water, bromine, various liquefied gases, including chlorine, carbonic anhydride, cyanogen, sulphurous anhydride, hydrochloric, hydrobromic, and hydriodic acids; nearly all melted fats and resins, fused iodine, sulphur, phosphorus, realgar, &c. Amongst the inferior conductors are aqueous solutions of gum, sugar, ammonia, boracic acid, mercuric cyanide, and alcoholic solutions of metallic salts; also melted boracic acid, and fused glass. Amongst the best conducting compound liquids are aqueous solutions of salts of the alkali metals, and of copper, silver and gold, and especially certain fused salts, *e.g.*, argentic fluoride and chloride.

According to Hittorf, the degree of resistance of a liquid

Digitized by Google

to electrolysis is dependent upon the difficulty with which the molecules exchange their constituents. Those which have active chemical properties should therefore conduct the best. Bleekrode contests this view.

**Nomenclature.**—The electrical decomposition of liquids is termed *electrolysis;* the conductor by which the current is said to enter the liquid is called the *anode*, and the one by which it leaves it is termed the *cathode*. The products into which the liquid is decomposed are called *ions*, those which appear at the anode being *anions*, and those at the cathode *cations*. Non-metals, acids, and peroxides are usually anions, while metals and alkalies are cations; electro-negative bodies, therefore, usually appear at the anode or positive pole, and electro-positive ones at the cathode or negative pole. The same elementary substance, however, may appear at the positive pole in one case, and at the negative pole in another, according to the circumstance whether the body it is combined with is more positive or more negative than itself. For instance, iodine, when combined with a more positive body, such as hydrogen in hydriodic acid, appears at the anode; but when combined with a more negative one, such as oxygen in iodic acid, it appears partly at the cathode. Sulphur in suitable different combinations exhibits the same variation. Hydrogen is almost the only gaseous cation.

**Visible Phenomena of Electrolysis.**—The phenomena usually seen in a liquid during electrolysis are—at the anode, corrosion with or without solution of the anode, gas is evolved, the anode acquires an insoluble coating, &c. In some liquids the anode becomes fragile, and falls to powder; in others it flies to pieces, but this is a rare case. Silver in dilute hydrofluoric acid is an example of the former, and wood charcoal in anhydrous hydrofluoric acid is an instance of the latter. At the cathode, a soluble substance is set free and dissolves, or a gas, a liquid, or a solid is liberated, and is either absorbed by the cathode, or adheres to it, or is dissolved by the liquid, or escapes. The layers of liquid also in contact with the electrodes frequently alter in specific gravity, that at the anode usually becomes heavier, and descends, and that at the cathode lighter, and ascends.

Faraday, by passing an electric current upwards through a strong solution of "Epsom salt" into a layer of distilled water lying upon it, observed that a layer of magnesia formed at the upper surface of the lower liquid where it touched the water, as if the water acted as a cathode. Daniell also subsequently passed an upward current of electricity through solutions of the nitrates of silver, mercury, and lead, and of the sulphates of palladium, copper, iron, and magnesium, into a dilute one of caustic potash, separated from them by a thin horizontal diaphragm of bladder. Oxygen was determined to the upper, and the respective metals to the lower surface of the diaphragm, and coatings of metal, more or less oxidised, were formed against the latter surface, the oxidation being more complete the more oxidable the metal; with the magnesic solution a coating of oxide alone was formed. More recently (*see Proceedings of the Royal Society* Nos. 212, p. 84, and 217, 1881, p. 142) I have stated, and shown by suitable experiments that "every inequality of composition, or of internal structure of the liquid in the path of the current must act to some extent as an electrode," and have also shown that a variety of phenomena take place at such a surface of mutual contact of two liquids when an electric current passes through it.

**Movements of Liquid Electrodes.**—As early as the year 1801 Gerboin observed the peculiar twitching movements of mercury whilst undergoing electrolysis, and which are now known to be due to electro-chemical action, and subsequently Sir H. Davy, Sir J. Herschel, and others investigated them. These movements are due to the formation and destruction, attended by contraction and expansion, of films upon the mercury, and would probably occur with other metallic electrodes, whilst in the liquid state in suitable liquids. (*See* Gmelins's "Handbook of Chemistry," Vol. I., pp. 381-384).

**Sounds Emitted during Electrolysis.**—Whilst investigating these peculiar movements and the thermic changes of electrolysis, I discovered that in certain liquids a humming sound is emitted by electrodes of mercury, and that the surface of the mercury is covered with minute waves during the passage of the current. I also found that the current was intermittent during these vibrations (*see Proceedings of the Royal Society*, 1862). Sounds are not unfrequently emitted also from other metals whilst depositing, *e.g.*, from antimony. These are sometimes produced by contraction and cracking of the metals, at other times by explosion of bubbles of gas.

**Decomposability of Electrolytes.**—The degrees of facility with which different electrolytes are decomposed are different. Faraday has given the following order, the first-named being the easiest:—Solution of potassic iodide, fused chloride of silver, of zinc, of lead, melted iodide of lead, hydrochloric acid, dilute sulphuric acid. Smee gives nitric acid, solution of chloride of gold, nitrate of palladium, chloride of platinum, argentic nitrate, cupric sulphate, stannic sulphate, dilute sulphuric acid, solutions of the sulphates of cadmium, zinc, nickel, iron, and magnesium, and those of salts of the alkalies generally. Dilute sulphuric acid offers less resistance to electrolysis than one of zinc sulphate, and more than one of cupric sulphate (Favre-*Comptes Rendus* Vol. LXXIII.; *Journal of the Chemical Society*, second series, Vol. X., p. 113). I have repeatedly observed that hydrochloric acid is decomposed more readily than water, and water more easily than hydrofluoric acid, also a solution of selenic acid before one of selenate of nickel. The readiness of decomposability of an electrolyte depends upon several conditions, and especially upon the nature of the electrodes; thus a solution of potassic cyanide is readily decomposed when the anode is composed of palladium, silver, or copper, but with difficulty when it is formed of iron or platinum. A large field of research exists in this part of the subject.

The decomposability of a liquid is usually increased by rise of temperature. It is also influenced by the length of the liquid portion of the circuit, which is the part in which the greatest resistance exists to the passage of the current. This has been shown by Gladstone and Tribe, who decomposed water by immersing in it a pure zinc plate previously coated electrolytically with a loose deposit of spongy copper or platinum, when two plates of those metals connected together and immersed at a distance from each other in the liquid would not decompose it, and have thus shown that "the dissociation of a binary compound may take place at infinitesimally short distances, when it would not take place where the layer of liquid is enough to offer resistance to the current" (*Proceedings of the Royal Society*, Vol. XX., p. 219).

According to Helmholtz, electrolysis of water by a voltaic current is possible only when the chemical processes in the battery, taken together, can produce more heat than the oxygen and hydrogen generated in the voltameter, and therefore that about $1\frac{3}{4}$ Daniell cells are required for a continuous decomposition of water. A single Daniell connected with platinum electrodes in dilute sulphuric acid produces only polarisation, no visible decomposition, the voltameter acting as a condenser of immense capacity (*Journal of the Chemical Society*, second series, Vol. XI., p. 463). As a matter of fact, however, a feeble current passes if the water in the voltameter contains dissolved oxygen, or the platinum plates occluded hydrogen.

According to D. Tommasi, "in order that decomposition may take place when a current passes through several electrolytes, it is necessary that the quantity of heat should be equal to the sum of the quantities absorbed by each electrolyte, plus the quantity necessary to overcome the total resistance of the electrolytes. By heat produced by the battery is meant that transmissible to the circuit. In many cases in which there is no decomposition when both electrodes are of platinum, decomposition takes place when the anode consists of some oxidable metal, such as copper or tin." "Of two compounds, that one is decomposed by preference which requires the least thermic energy" (*Journal of the Chemical Society*, Vol. XLII., 1882, pp. 134, 353, 789, 1,019, 1,155, and 1,156; *see* also Favre, "Watts's Dictionary of Chemistry," Vol. VII., p. 458).

On the subject of "The Limits of Electrolysis," consult

Digitized by Google

Berthelot (*Journal of the Chemical Society*, Vol. XLII., 1882, pp. 260 and 353).

According to E. Obach, liquid mixtures of metals do not suffer electrolysis. His experiments were made with alloys of sodium and mercury, of sodium and potassium, and of tin with lead. The portions of alloy around the poles after passage of the current were unaltered in chemical composition (*Journal of the Chemical Society*, 1876, Part II., p. 37. *Chemisches Central Blatt*, 1875, p. 497).

Conduction in Electrolytes without Decomposition.—Whether this takes place or not is an important question, and after many researches on the subject electricians are even now not unanimous respecting it. According to Favre's experiments (*Comptes Rendus Academie des Sciences*, Vol. LXXIII., p. 1,463), true conduction without electrolysis does occur when two Smee cells are used to electrolyse dilute sulphuric acid. In the electrolysis of fused argentic fluoride, also with sheet silver electrodes, I observed that the liquid conducted the current with a most extraordinary degree of facility, apparently out of all proportion to the weight of metal deposited. Conclusive experimental evidence is, however, still much required to settle the question. With a current of insufficient electromotive force to decompose an electrolyte, either the electric charges must accumulate on the electrodes, and the liquid act as a dielectric, or they must be transmitted by convection or conduction.

(TO BE CONTINUED.)

## THE EVOLUTION OF DYNAMO MACHINES.

BY JOHN T. SPRAGUE.

1. The doctrine or idea of evolution is now firmly grafted upon the scientific mind, and is extending itself into all the departments of knowledge. It teaches us that nothing is isolated; every fact, every idea, holds some relation to others from which it grows, while it becomes a point of origin for others, sometimes continuing a direct line, sometimes constituting a point of differentiation, at which may originate several growths, proceeding onwards until there appears no relationship between their products. Such is the relationship among the various languages of mankind, as well as among the races of beings. Now, an important effect of this is that not only may the untrained mind be unable to see a connection between two apparently distinct things, but that there may actually exist *gaps in the line of evolution*, missing links in the chain, either lost, or which never had actual existence, except in the rudimentary condition.

2. In chemistry we have a number of "homologous series" and groups of series, which illustrate this very remarkably. Thus we have a series of radicals starting from methyl $CH_3$, and rising by the successive additions of $CH_2$ through a long line of substances, which gradually become denser; the addition of hydroxyl HO to any one of these substances converts it into a corresponding alcohol, such as the commonly known alcohol, the hydrate of ethyl, $C_2H_5OH$, and glycerine, not commonly considered alcoholic in character, yet really so scientifically. Another atom of oxygen inserted in the molecule, in place of $H_2$, gives us the corresponding acid, such as the acetic acid of vinegar $C_2H_3OOH$ up to stearic, and the waxy acids, and so on.

3. These same groups and subtances may be classified upon other systems, such as that of types, but still with the same results which are now under consideration, the construction of connected lines and diverging groups, forming a clearly connected whole, in which, however, there are many gaps—substances which do not actually exist in nature, or have not been discovered, but the possibility of whose existence is evident, while some of them have actually been produced artificially in consequence of this foreseen potentiality of existence.

4. It is this relationship that I wish to present, not as a matter of fact, not as implying that the inventors of the different forms actually developed them in this manner knowingly, but as essential to the understanding the resemblances and differences among the machines, and as enabling future workers to proceed upon definite principles, rather than upon rule of thumb processes and costly tentative experiments.

5. The first thing in development of correct ideas is to clearly distinguish between *things* and *appearances*, between fundamental principles and mere forms of construction. Thus to begin with, there is no real difference between a bar magnet and a horseshoe magnet, except in the form of the *field of force* set up between the poles, which adapts one form to some purposes and the other form to others. Thus it is evident that Fig. 2 is merely Fig. 1 with its two ends turned up by bending the middle, which allows the lines of force connecting N and S to be shortened, the resulting field to be reduced in area, and consequently increased proportionally in intensity.

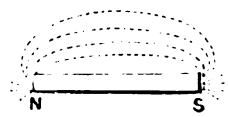

FIG. 1.

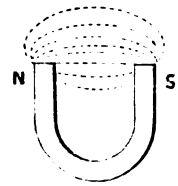

FIG. 2.

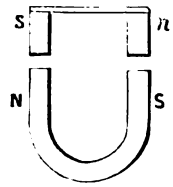

FIG. 3.

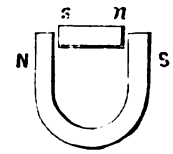

FIG. 4.

6. It is less obviously, but equally true that an electromagnet armature rotating over the poles of a magnet, as in Saxton's machine, or across the poles, as in Clarke's, acts precisely as does a straight bar electro-magnet passing between the poles, as in the Alliance and other machines. Thus Figs. 3 and 4 differ in no way in type and action; nor do the Clarke and Alliance machines. The differences relate to mechanical construction, and to the most effective way of taking up the lines of force of the magnet. In all these forms the action is merely the placing of the iron of the armature in such position as will concentrate within its own mass as much as possible of the external field of the magnet and diminish its independent external actions.

7. It may be remarked here that each passage of the armature not only causes some molecular change in itself while taking up magnetism, but that it also causes a change in the molecular conditions of the magnet itself. If a wire is coiled upon the magnet, a current will be set up in it at each passage; in fact many apparatus, such as fuse exploders, are constructed upon this principle; the poles of the magnet themselves are wound with wire, and the current is produced by applying an armature and forcibly withdrawing it.

8. The changes of the magnetic field may be made evident by a telephone based upon a soft iron bar, which being applied to the magnet will be magnetised strongly when the armature is distant, and lose its force as the external lines concentrate in the approaching armature; at each such change a sound will be given forth. The efficiency of any armature may be tested by the reduction it produces in the external field, as shown by the diminished deflection upon a magnetic needle at a little distance.

9. One stage of evolution from the mere bar is a radial armature, which Fig. 5 shows is merely a multiplication of the bars of Fig. 4. The fact of its rotation in the plane of the poles N S, instead of across them, as in the disc form of armature, is a pure matter of construction, and this gives us one of the Lontin machines, which is built of a series of such radial systems, slightly overlapping each other, so that the field is transferred into one after another of the collection of bar electro-magnets which constitutes the complete armature system.

10. Another step combines the single ring of radial bars of

Digitized by Google

Fig. 5, not with a single field magnet, but with an equal number of alternating field poles. We have then precisely the conditions of the Alliance type, different as the machines appear. If we look at Fig. 6 this is evident. It is of no consequence as to theory how the several poles N S of the field magnets are related; those at opposite points may complete the horseshoe, and then the two radii of the armature constitute a straight bar between its poles.

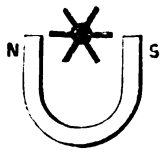

Fig. 5.

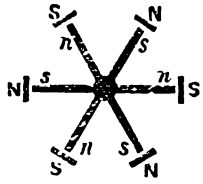

Fig. 6.

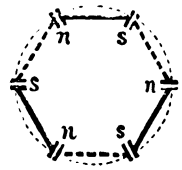

Fig. 7.

But let us consider adjoining poles N S as forming each a separate field magnet; then the two adjoining radii form its armature (all being supposed to unite at the middle), and these, therefore, constitute a horseshoe electro-magnet.

11. This leads to a new stage of evolution, which develops an apparently distinctive type, still depending on the same principles. We know (Sec. 1) that a straight bar and a horseshoe are the same in principle. We take, then, each adjoining pair of radii, acting as a horseshoe, but in no way differing in principle from the opposite radii, forming a bar armature to the *opposite* poles N S. We straighten this horseshoe so that it shall become a bar armature to the adjoining poles N S, and thus we develop the three bars of Fig. 7 and spaces, which we can fill up with three similar bars, shown in dotted lines. Curve the bars a little outwards, as also shown in dotted lines, and we have what looks like a ring armature, but is so only mechanically. Electrically, it is a hexagon system of independent armatures, arranged in pairs so as to divide the forces of the field poles between them, and form a succession of consequent poles in the ring thus constituted.*

12. This is, however, a very important stage of the evolution, for it is the basis of three machines wholly distinct from each other. 1. Fig. 7, as rounded off, gives us the armature and the principle of the De Meritens magneto-electric machine. 2. Fig. 7, in its preliminary hexagon form, is the elemental ring of the Bürgin machine; this is often but wrongly described as a compound Gramme machine. The fact that the Bürgin armature is materially constructed of a continuous iron ring is a detail of manufacture (though it has also other results not belonging to the present topic). Theoretically each segment is an independent bar electro-magnet, fitting to and polarised by the extremities of the field magnet poles. 3. Again, as a ring, and also as a continuous metal core, Fig. 7 gives us the Brush armature, which is also composed of independent electro-magnets, and in so far is different from the true continuous ring of the Gramme type; it does not, however, approach a stage further towards it by a continual interchange of sub-segments successively building up the actual bar, and by reverting to the bi-polar field system.

13. At the next stage of evolution we pass from the *apparent ring* of Fig. 7 to the true ring of the Gramme or Pacinotti type. In all the preceding forms independent poles have been created and reversed completely, and the wire of each segment has had its resulting succession of reversed electric impulses set up within it and collected from it. But the essence of the Gramme ring is that, while mechanically and structurally the iron core rotates, and the iron is continually undergoing changes of magnetic state, the *true core* —the receiver of the lines of force of the field magnet poles —is stationary, and the typical action consists in drawing turns of wire across the lines of force when they pass from field poles to armature on one side and from armature to field poles on the other side, the wire itself changing direction as it changes sides.

This is only one of the specialities of the Gramme ring, but it is the one which brings it into the line of evolution now being studied.

(TO BE CONTINUED).

* This same ring may be derived also from the disc of bars by turning these round upon their middles, so as to bring their ends into relation with adjoining opposite field poles, instead of poles on opposite sides of disc, related to the ends of the single bars.

## ELEMENTARY ELECTRICITY.—XVI.

(CONTINUED FROM VOL. XI., P. 535.)

The electromotive force of a battery can be determined by means of a quadrant electrometer, the deflection produced by the battery being compared with that produced by some standard cell of known electromotive force. If the electrometer be of the standard (White's) pattern, the electromotive force can be determined in volts at once, because the needle is always charged to the same potential, as indicated by the idiostatic gauge. With the simple forms of the instrument the deflection produced by the standard cell must be observed immediately before or immediately after that produced by the battery whose electromotive force it is desired to measure.

Methods of measuring the resistance of a battery will be discussed later on.

The rate at which a battery polarises when sending a current through a circuit of any given resistance may be roughly determined by allowing a tangent galvanometer to form part of the circuit, and noticing how the deflection is reduced as time elapses. A considerable amount of polarisation takes place, however, before the galvanometer has time to reach its proper deflection, so that this method fails to give an accurate result. A better method is to measure the resistance of the battery; let this be denoted by $r$. Then observe the deflection of an electrometer when connected directly with the poles of a battery; this gives the whole E.M.F., $E$, of the battery, the poles being insulated. Then connect the poles with a wire of resistance, $R$, and suppose the deflection of the electrometer falls immediately to $e$; then the whole electromotive force in the circuit is to $e$ as the whole resistance in circuit is to that between the ends of the wire, *i.e.*, as $R + r : r$. Hence the electromotive force, when the whole resistance in circuit is $R + r$, is $e\,\frac{R+r}{R}$, and the difference between $E$ and this amount gives the loss of E.M.F. due to immediate polarisation. By continuing to observe the deflection of the electrometer we can learn how the E.M.F. goes on diminishing as the current continues to flow. This method assumes that the resistance of the battery remains constant, which is not quite true.

The electromotive forces of batteries may also be compared by employing the batteries successively to charge the same condenser and discharging the condenser through a galvanometer of great resistance. Instead of sending the whole of the charge of the condenser through the galvanometer in each case, it is best to shunt the galvanometer with a shunt of considerable resistance, and vary the shunt so that the kick of the galvanometer is the same for each battery. We then know that the quantity of electricity discharged *through the galvanometer* is the same in each case. Then, knowing the resistances of the galvanometer and shunts, the whole charges of the condenser can be compared, and hence the electromotive forces of the batteries. For example, suppose that the resistance of the galvanometer being G ohms, a certain kick is observed when a shunt of $S_1$ ohms is employed with the first battery, whose E.M.F. we will call $E_1$, and that the same kick is obtained with the second battery when the resistance of the shunt is $E_2$. Let C denote the capacity of the condenser; then $E_1 C$, $E_2 C$ will be its charges in the two cases. Then when the shunt $S_1$ is employed the quantity of electricity going through the galvanometer is to the whole charge of the condenser as $S_1$ to $S_1 + G$, and is therefore equal to $\frac{S_1}{S_1 + G} E_1 C$. In the second case the quantity

Digitized by Google

passing through the galvanometer is $\frac{S_2}{S_2 + G} E_2 C$, and if the kick be the same these two quantities must be equal.

Hence

$$\frac{S_1}{S_1 + G} E_1 C = \frac{S_2}{S_2 + G} E_2 C,$$

or

$$\frac{E_1}{E_2} = \frac{S_2 (S_1 + G)}{S_1 (S_2 + G)}.$$

Inasmuch as the condenser is always charged to the ful electromotive force of the battery, the flow of electricity into the condenser having always ceased before contact with the battery is broken, it follows that the accuracy of this method is not affected by the resistance of the battery or its tendency to polarisation. The comparison obtained is that of the electromotive forces when the batteries are insulated.

The charging and discharging of the condenser can be readily effected by means of a Morse key. One armature of the condenser is permanently connected with the negative pole of the battery to be tested, and with one electrode of the galvanometer. The other armature is connected with the body of the key, the positive pole of the battery with the back cushion of the key, and the second electrode of the galvanometer with the front cushion. When the key rests on the back cushion the condenser is charged from the battery, one electrode of the galvanometer being insulated; and when the key is depressed the condenser is discharged through the galvanometer (and shunt), the positive pole of the battery being insulated.

Another method of comparing the electromotive forces of batteries depends upon the condition with respect to potential of a wire through which a constant current is flowing. If any two points be selected upon such a wire the current flowing from one to the other is directly proportional to their difference of potential, and inversely proportional to the resistance of the wire between them. Hence, if there be no leakage, so that the same current flows through the whole length of the wire, it follows that the difference of potential between any two points must be proportional to the resistance of the portion of wire between them, and the potential of the wire must diminish uniformly per unit of resistance as we pass along the wire in the direction in which the current is flowing. (If the wire be straight and of uniform section the statical charge on the surface of the wire, which maintains this difference of potential, must also diminish uniformly as we pass along the wire in the direction of the current. It is this statical charge, which must be communicated to the surface of the wire before the current becomes steady, that renders the capacity of a submarine cable a matter of great importance as affecting the "speed of signalling.") This uniform variation of potential per unit resistance along a wire conveying a steady current enables us readily to find points upon such a wire whose potentials differ by any amount not greater than the difference of potential between the extremities of the wire; and the difference of potential between any two points can be very accurately compared with that existing between any other two points. Hence, if a sufficiently powerful battery be employed to transmit the current, two points may be found upon the wire whose potentials differ by an amount equal to the E.M.F. of any one of the batteries to be compared, and if the terminals of the battery be connected with these points, the battery will be in equilibrium without any current flowing through it. The method of making the comparison between the batteries will then be as follows:—

A battery more powerful than any of those to be compared is made to send a current through a wire of great resistance, (generally a set of resistance coils contained in one or more boxes). The battery serves to raise one end of the wire to a much higher potential than the other, so that there is a uniform fall of potential per unit resistance along the wire. Now, suppose that a separate cell is connected with two points, A and B, of the wire, and that the difference of potential between these points is equal to the E.M.F. of the battery, and let the positive pole be connected with the point of higher potential, and the negative pole with the point whose potential is lower. The battery will then be in equilibrium, and there will be no tendency for a current to flow through it in one direction rather than the other. If the difference of potential between A and B is less than the E.M.F. of the cell, a current will flow through the cell in the same direction as if its poles had been directly connected, *i.e.*, from the zinc to the copper (platinum, carbon, &c.) through the liquid, but if the difference of potential between A and B be greater than the E.M.F. of the cell a current will be forced through the cell in the opposite direction. A galvanometer and a key are introduced with the battery between A and B and one of the points, A, B, is moved along the wire till the galvanometer shows no deflection on making contact with the key, but the whole resistance of the principal circuit, and therefore the current in it, is left unaltered. When resistance boxes are used the plugs are taken out or inserted between A and B, and corresponding plugs inserted or taken out in the rest of the circuit, and this is equivalent to moving A or B along the wire. Suppose that $C$ is the constant current (unknown) which flows through the circuit, and $r$ the resistance between A and B along the principal circuit when there is no deflection of the galvanometer. Then the difference of potential between A and B is $Cr$, and if $e$ denote the E.M.F. of the cell we must have $e = Cr$.

Now, suppose another cell inserted whose electromotive is $e'$ in place of the cell whose E.M.F. is $e$. Let the necessary adjustments be made, as before, as rapidly as possible, and let $r'$ be the resistance between A and B when the galvanometer is unaffected. Then, $e' = Cr'$. Hence, $e : e' :: r : r'$, and the unknown current $C$ does not appear in the comparison. In this way any number of cells can be compared in rapid succession. The method is a modification of Poggendorff's compensation method, and the apparatus is sometimes known as Latimer Clark's potentiometer.

If the whole resistance in the circuit of the primary battery be known, including that of the battery itself, we can then compare the electromotive force of the large battery with that of any battery connected with A and B, but it must be noticed that the comparison is made between the two batteries when one of them is sending a current but the other has no current flowing through it. The E.M.F. of the second battery may therefore be regarded as constant, while that of the first battery will change with the resistance in circuit as well as with the lapse of time, on account of polarisation. The method therefore enables us to determine the effects of polarisation on the large battery.

For example, suppose that the second battery is a standard Daniell cell, whose E.M.F. may be taken as 1·07 volts, and suppose that the whole resistance in the primary circuit, including that of the large battery, is 10,000 ohms. Suppose that when the galvanometer gives no deflection, the resistance between the points, A and B, to which the galvanometer and Daniell cell are connected is 2,000 ohms. Then the electromotive force of the large battery is five times that of the Daniell cell, *i.e.*, 5·35 volts, the battery at the time sending a current through 10,000 ohms.

Now, suppose that the resistance of the whole circuit is reduced to 100 ohms, and that when there is no deflection of the galvanometer the resistance between A and B is 22 ohms. Then the E.M.F. of the large battery is $\frac{100}{122} = 4\frac{6}{11}$ that of the Daniell cell, or nearly 4·85 volts, and it has lost ·5 volt by polarisation on account of the increase of the current. After the current has been flowing for ten minutes it may be found that the resistance between A and B has to be increased to 25 ohms, showing that the E.M.F. of the large battery has been still further reduced and is now only 4·28 volts. After this the falling off of the E.M.F. may be found to be small during a considerable interval.

In the same way the E.M.F. of the large battery may be tested when it is sending a current through 10 ohms, or any other resistance, but when the whole resistance in the circuit is small a considerable error is likely to occur on account of the uncertainty as to what the internal resistance of the battery itself may be.

If a current is sent through a solution of copper sulphate between platinum plates the salt is decomposed,

Digitized by Google

copper being deposited on the cathode, and oxygen liberated at the anode, while free sulphuric acid is formed in the liquid. Hence an amount of work has to be done equivalent to the energy of combination of the copper with the oxygen and sulphuric acid. If, however, the current is sent through the copper sulphate solution, the electrodes themselves being copper plates, copper is deposited on the cathode, but instead of oxygen and sulphuric acid being liberated at the anode, the copper plate is itself dissolved and copper sulphate formed. Thus, the amount of copper sulphate in the solution remains unchanged, and on the whole no work against chemical affinity is done in the cell. Hence, it may be expected that a very small E.M.F. will be capable of decomposing the copper sulphate, since the only work it has to do is the mechanical carrying of the copper from the one plate to the other. Experiment shows that this is the case, and that the amount of polarisation of the electrodes which occurs is very small indeed. There will still be some polarisation, for the electrical properties of the electrolytically deposited copper are slightly different from those of rolled copper, and, moreover, depend on the rate at which the copper is deposited, and therefore on the amount of current per unit area of the electrodes. Similar conditions obtain whenever a metallic salt in solution is electrolysed by a current from electrodes of the same metal. Thus, in electrotyping, a copper anode is employed; in electro-plating, a silver anode; in electro-gilding, a gold anode; and in nickel-plating, a nickel anode. By this system there is a saving of electrical energy, while the strength of the solutions is kept up by the metal dissolved from the anode.

Secondary batteries are electrolytic cells in which a large amount of energy is transformed from electrical energy into the energy of chemical separation. It has been stated above that, if two platinum plate are dipped in dilute sulphuric acid and connected with the poles of a battery, nascent hydrogen will accumulate upon one plate and oxygen upon the other, and so removing the battery and connecting the platinum plates with a galvanometer a current will flow for a short time. But the oxygen and hydrogen begin to escape from the platinum plates before any great amount of energy can be stored in this way. If the gases be collected in suitable receivers, so that part of each platinum plate remains immersed in the gas, we have Grove's gas battery, which is capable of sustaining a current for a considerable time after removing the primary battery and until the gases have recombined.

In 1860, Planté employed lead plates instead of platinum plates, and by repeatedly sending a current through the cell in opposite directions he produced a considerable layer of peroxide of lead on one plate while the other was converted into a spongy condition for a short depth below the surface; the spongy lead being reduced from the oxide previously formed. On connecting the plates a current flows through the acid from the spongy metal to the oxidised plate until both plates are reduced to the same state of oxidation. On sending a battery current through the cell the former state of affairs is reproduced, and the secondary battery is again capable of sending a current. As a considerable quantity of oxide of lead is formed a cell of this description is capable of storing a large amount of energy ready to take the form of electrical energy as soon as the circuit is completed.

In 1880, Faure improved upon Planté's cell and simplified its construction by artificially coating each plate with a layer of red lead. On sending a current through the cell the red lead on the cathode is reduced to the condition of spongy lead, while that on the anode is converted into brown (or per —) oxide. On connecting the plates by means of a wire a current flows until the plates are both reduced to their original conditions.

It appears that when the Faure cell is discharged the lead oxide combines with the sulphuric acid, forming lead sulphate, but on charging the cell the sulphuric acid is again liberated to allow of the formation of metallic lead and of peroxide. Hence the extent to which the cell is charged may be determined by estimating, with a hydrometer or otherwise, the amount of sulphuric acid in the liquid, the quantity of free acid diminishing as the energy stored in the cell is increased.

## CORRESPONDENCE.

### SEPARATING METALS BY ELECTROLYSIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The attention of our client, Mr. Henry R. Cassel, of New York, having been called to the Note in your last issue on "The New Method of Separating Metals by Electricity," we are requested to inform you that Mr. Cassel is the sole inventor and the patentee of the process which you describe, under letters patent granted to him on the 26th September, 1882, and numbered 4580.

We are also instructed that Mr. Atkins, whose name you mention as the inventor, was until a very recent date in the employ of our client in America, and so gained such knowledge of the subject as he may possess; but neither he nor the Electrolysis Company have any patents, and proceedings are now pending in regard to Mr. Atkins's attempts to make use of our client's invention.

We trust that, in fairness to Mr. Cassel, you will give this letter a place in your columns, as the statement in your Note that another person is the inventor of the process is likely, if not publicly contradicted, to operate to the detriment of our client, who is now in this country making arrangements for the introduction of the invention.—Yours, &c., WATNEY, TILLEARD, AND FREEMAN.

34, Clements-lane, Lombard-street, London, E.C.,
12th November, 1883.

### DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The reason why your correspondent's dynamo will not work is because he has, according to his letter, "short-circuited" the poles of his machine by connecting them to an iron bed-plate, thus causing most of the lines of force to pass through the iron plate and very few to pass through the armature. The field magnet should be bolted to a piece of hard wood or non-magnetic metal, such as brass or zinc. He should also run the machine at a much higher speed, at least 2,000 a minute, to obtain anything of a current.

For a series machine the resistance of the field magnets should be three-quarters that of the armature.

Nos. 18 or 20 wire would be better for the armature than 16.

For a shunt machine the resistance of the field magnets is generally made some hundreds of times greater than that of the armature, but varies according to size and type of the machine.—Yours, &c., W. M. H.

### LIGHTING CARRIAGES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should like to know the cost of lighting the lamps of a brougham by means of accumulators and incandescent lamps. I should also like to know the probable weight of the accumulators.

On looking through Vol. X. of your valuable paper, I notice that Messrs. Ayrton and Perry write, under date November 22, 1882, that "they have lighted three lamps by three accumulators, each weighing 14lb.;" but I suppose that there will have been a great improvement made on that weight since then.

If you or some of your numerous readers will kindly answer the above, I shall feel obliged.—Yours, &c.,

Water-lane Dye Works, Bradford, GEO. H. FRANCE.
November 2, 1883.

UTILISATION OF NATURAL FORCES.—*Erratum*—Near the end of the article on this subject, page 606 of our last impression, line 6 from end, "get 10 horse-power," should have been printed "get $\frac{1}{10}$ horse-power." The context, however, points to the typical error.

## SKELETON TELEGRAMS.

For some time past the curious student of foreign intelligence has been astonished at the lavish expenditure on international cabling, and perhaps a little shocked at the amount of false or fanciful information disseminated by that agency. It has now, however, pleased one of the associations engaged in this kind of business to enlighten the world as to how the thing is done. The world did not ask to be cured of its illusion; it probably would have preferred to read its foreign telegrams with continued confidence and wonder. But for reasons no doubt sufficiently cogent to the Central News, though unintelligible to everybody else, its customers can no longer be credited with an extravagant outlay on their news columns, nor with over scrupulous care for the truth of what they publish. The Central News thinks itself libelled by a cartoon which recently appeared in one of the London comic papers, representing a bogus telegram agency, and labelling it, "Chartered L——." Had the caricaturist been content to stop at this there would have been no libel, for even the sensitive conscience of the Central News would not deny that liberties have been taken with telegrams sufficient to justify the epithet libertine. But the letterpress explicitly suggested a shorter word beginning with the same letter, and it is a breach of the law to call even a news agency a liar.

As the offence is admitted and defended on public grounds, we are not debarred from commenting on certain aspects of this most remarkable case. What amount of damages a jury will inflict remains to be seen; the injury done by the defendant in its incautious zeal for purity of news-vending may have been considerable, but it can hardly exceed what has been self-inflicted by the revelations of the prosecuting agency. Under cross-examination it confesses to having received on a particular morning two telegrams from Canada, containing sixteen words and twelve words respectively. They were not in code or cypher, but in what is called skeleton form—that is to say, the utmost possible information was conveyed in the fewest possible words. Within the limits mentioned the information was necessarily of the meagrest; what there was of it is said not to have been true, but with that we have nothing to do. True or untrue, the editing staff of the Central News took the cablegrams in hand and subjected them to a process of what the prosecuting counsel called winnowing, which the defending counsel calls expanding, but which the editor himself prefers to call filling in. The filling in appears to be done on a liberal scale on these occasions, the one telegram, when handed to the newspapers for publication, having assumed the dimensions of 330 words, the other 710 words. The result was that the public were startled with news of a most alarming description, the more so because the details were so full and circumstantial, and the descriptions so graphic and seemingly truthful.

The most painful part of this business is that the prosecutors declare they have followed a well-established custom, and in effect assert that, when the news agency does not "fill in," the newspapers do it themselves—in other words, that newspapers and telegraph agencies alike combine to persuade the public into the belief that they expend a lot of money in cablegrams when in reality they spend very little. For this, at bottom, is plainly the effect of these manipulations. A brief telegram made readable is one thing, a skeleton telegram of doubtful meaning rendered sensational, picturesque, and veracious is another. The public are not children, and though they may need a simplified rendering, which is quite legitimate, they do not ask for details supplied from an editor's back parlour. Who, then, does want these details? Evidently either the newspapers or the news agencies, for the obvious purpose, not of informing the public, but of deluding it. These big guesses, which are made to amplify and elaborate the skeleton cablegram, are designed in the interest of competitive enterprise; obviously they cannot often avoid the pitfall of competitive exaggeration, and the public are now pretty well informed as to what that means.

It is some satisfaction to note that the cable companies who have to transmit these skeleton telegrams at a very low figure are in no way to blame for the state of affairs which this trial has revealed. The rates are extremely low—some people consider them far too low. On the score of expense there is no excuse for such parsimony as that which curtails a despatch of great public interest and importance—if it has any truth in it—down to the size of a report of the state of the weather. Somebody must profit by the excessive economy of the newsvendors; but it is certainly not the cable proprietors. We wonder what the newspapers would say to the cable companies setting up an editorial room, and "filling in" according to taste matter which had not travelled over the wires, but charging for it as if it had. Not that we insinuate that the news agencies receive their payments on that scale. But either they do distribute their news as telegraphic matter, or else they submit it as edited matter. One would be curious to know which, and whether the newspapers would be willing to pay for longer and more trustworthy intelligence if the companies could supply it

Digitized by Google

on reasonable terms. Meanwhile, they suffer in more ways than one; they have to transmit telegrams which are exceedingly troublesome to manipulate accurately, and for which they receive very inadequate remuneration, and when they have done this they incur a great part of the odium implied in such libellous cartoons as that which *Judy* has indulged in. For undoubtedly the tendency of all startling information purporting to come by cable telegraphs, but which afterwards proves to be false or exaggerated, is to discredit the telegraph system altogether, and to render its services neither trusted nor demanded. A "lying telegram" is an epithet we have heard only too often of late, and it is one which those who are interested in the welfare of the telegraphs naturally resent with some warmth. Their chief hope of redress will be in the course which the newspapers themselves may now take in regard to this class of telegrams. The remedy is in their hands. They can demand to have the fuller version accompanied by the original skeleton; or they can content themselves with the skeleton, filling it up in their own fashion; or they can make their bargain direct with the several cable companies. The old telegraph companies used to supply news as well as transmit it; they were not so ingenious, or so enterprising, or so imaginative, as some of the news agencies' correspondents, but we do not remember that they were ever accused of needlessly alarming the public, or of amplifying their despatches with details which turned out to be pure fiction.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

In the most general sense a dynamometer is an apparatus for measuring or indicating mechanical forces. The principle of the earliest contrivances was to simply weigh the force exerted by animals or machines, using for this purpose either counterweights or springs. An example of the former is the dynamometer constructed by Graham and improved by Desaguliers, which consisted of a steelyard, to the short arm of which a rope was attached conveying to the instrument the force to be measured, whilst a movable weight sliding upon the graduated long arm indicated by its position the magnitude of this force. But it was soon found that, with forces subjected to variations, as for instance in measuring the tractive power of animals, this instrument was difficult to handle, on account of its great unsteadiness, and the other method of counterbalancing the force by springs was resorted to. The earliest example on record is the dynamometer of Leroy, of the French Academy. This consisted of a metal tube closed at one end, and containing a spiral spring upon which rested one end of a graduated metal rod, the other end of which protruded some distance out of the tube and was furnished with a ball or knob. The force to be measured was applied to the ball, pushing the rod further into the tube until counterbalanced by the compression of the spring. Another example of a spring dynamometer is that made by Regnier. It consisted of an elliptical spring provided with hooks at the ends of the greater axis of the ellipse, the force being applied to these hooks in such way that it tended to elongate the ellipse, at the same time reducing its smaller axis. A dial, with a pointer pivoted to it, was fixed on one of the flat sides of the ellipse, whilst to the other was fixed a rod acting by means of a short crank on the pointer. The approach of the two flat sides of the elliptical spring, and therefore also the force pulling at the hooks, was thus indicated on the dial. It will be seen that this contrivance is essentially the same as our modern spring balance, notably that form which is sometimes employed as an intermediate link between chain and hook on cranes. Poncelet improved Regnier's instrument by substituting for the elliptical spring, which was difficult to manufacture, two flat springs fastened together by short links, and attaching the hooks in the middle of these springs. This form of spring balance was afterwards used by Morin in his researches on the laws of friction between solid bodies and also in his traction-dynamometer.

All these instruments were orginally designed to measure a static effort, but not mechanical energy or foot-pounds of work done per unit of time. There is, however, one partial exception, namely Leroy's, which could be used to measure the energy of a blow dealt on the ball, and which is used for this purpose even at the present day. The theory of this instrument is exceedingly simple. We know that a spring when compressed within its elastic limits will yield in proportion to the compressing force. Let in Fig. 1 the end E of the spring in its natural unstrained state be under O and assume the force, P keeps it compressed by the amount O A = $x$, then the magnitude of this force can be expressed by

$$P = \phi x,$$

where $\phi$ denotes a constant co-efficient depending upon the dimensions and material of the spring. By applying various forces to the knob (which is most conveniently done by setting the instrument upright and placing known weights on the top, account being also taken of the weight of the rod and knob), and noting on the rod the depth to which it is pushed into the tube, the instrument can be correctly calibrated, and the co-efficient $\phi$ found. During the time the blow lasts the pressure exerted by the rod upon the spring increases from nothing to a maximum, which can be indicated by a recording pointer in the form of a sleeve sliding on the rod. Let A be an intermediate position and B a position infinitely near to it, then the mechanical energy put into the spring by compressing it from A to B is $\phi x\, dx$, where $dx$ = A B.

In like manner we find the work necessary to compress the spring from B to C, and so on. By adding all these values, that is, by integrating, we find the total work of the blow

$$W = \int_o^a \phi x\, dx,$$

the integral being taken between the limits $o$ when the spring is not in compression, and $a$ when it is most compressed.

$$W = \phi a \frac{a}{2}.$$

As we have assumed that the rod is graduated to known weights, say, for instance, to pounds, we can read off on it by the position of the recording pointer the maximum of the compressing force due to the blow $F = \phi a$, and we find the total energy of the blow

$$W = F \frac{a}{2}$$

in foot-pounds by multiplying the force recorded by the pointer with half the distance in feet the rod has been pushed into the tube.

Neither Leroy's instrument nor the other dynamometers which simply weigh a static effort have much practical importance. It is not a *static* but a *dynamic* force which we desire to know if we are to judge of the power given out or absorbed by a machine. The important thing to know is the product of force exerted and space traversed by that force in a given time; and dynanometers in the more limited sense of the word are instruments which enable us to measure that product.

It is customary to distinguish between two classes of dynamometers—those which absorb the work given out by a prime mover, transforming it into some other form of energy, generally heat; and those which, being placed between a prime mover and the machine to be tested, do not absorb any appreciable amount of power themselves, but indicate how much power is flowing through them. The former are called absorption, the latter transmission dynamometers. Generally speaking, the absorption dynamometers are more especially applicable to the testing of prime movers—as, for instance, animals, water wheels, turbines, wind engines, steam and caloric engines, electro-motors, &c.; whilst the transmission dynamometers are best suited to the testing of power-

Digitized by Google

absorbing machines—as, for instance, mechanical tools, looms, pumps, ventilators, carriages, vessels, dynamos, &c. The application is, however, not strictly limited in this manner, for it is evident that a transmission dynamometer can be used to test a prime mover; and it will be shown further on how, for want of something better, an absorption dynamometer can be used to test machines absorbing work. Another class of instruments not coming precisely under either of the above heads, but as it were standing midway between them, must here be mentioned. It is the steam-engine indicator invented by James Watt, and improved by Macknaught. Its theory is so well known that it need not be repeated here, but it should be pointed out that the indicator is a dynamometer in the strictest

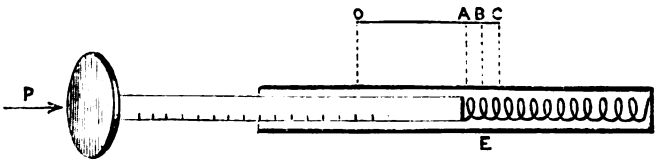

Fig. 1.

sense of the word. Imagine in Leroy's instrument (Fig. 1) the knob formed into a piston sliding in a cylinder which communicates with one end of the steam engine cylinder, then the position of a pencil attached to the rod will at any moment indicate the pressure of the steam propelling the piston of the engine. If a sheet of paper be drawn laterally across the pencil in a direction corresponding and with a speed proportional to the movement of the cross-head of the engine, the curve so traced on the paper by the pencil will enclose an area proportional to the work performed by the steam in pushing the piston of the engine.

*Absorption Dynamometers.*

The first instrument of this class was constructed in 1821 by Piobert and Fardy, who used it for measuring the power given out by water wheels. Prony was the first who adapted

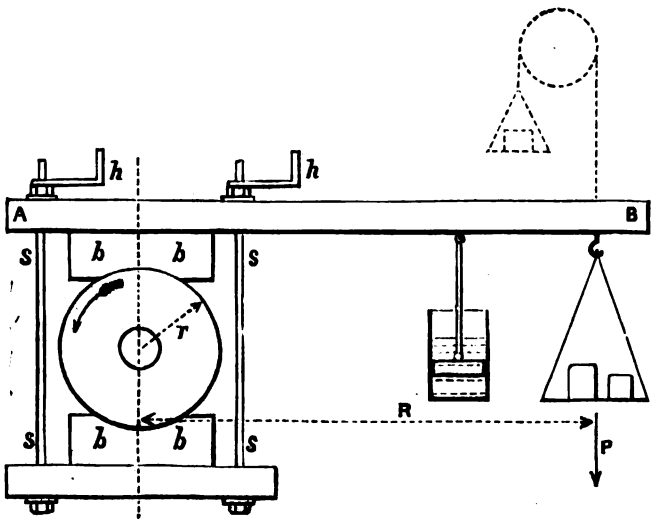

Fig. 2.

this instrument to the testing of steam engines, and since then it is commonly known as Prony's brake. In the original design wooden brake blocks rigidly connected to the end of a long lever were clipped to the shaft of the engine, and tightened by means of screws to the desired amount of friction. It was, however, found that on account of the smallness of the surfaces in friction only a very limited amount of mechanical energy could be conveniently absorbed, that is transformed into heat or used up in the destruction of the surfaces in frictional contact, and, therefore, in subsequent arrangements the brake was applied to the face of a special pulley keyed on the shaft. In this form it is used also at the present day. It consists of a strong beam, A B (Fig. 2), to which are fastened brake blocks, *b b*, of hard wood at one end, whilst the other can be weighted to any desired extent. The friction between the brake blocks and the pulley can be regulated by means of the screws *s s*, the top nuts of which are provided with handles, *h h*, for the purpose of being easily turned by an attendant. If the pulley revolves in the direction of the arrow there will be a tendency to lift the end of the lever, and this tendency will be the greater the more the screws are tightened. To prevent accidents through the lever being carried right round it is well to limit its motion by two fixed stops. Great care should also be taken to employ a pulley perfectly round and very stiff. If the pulley be slightly elliptical the friction will increase somewhat every time the larger axis of the ellipse passes under the brake blocks, thus making the apparatus jerky. To facilitate accurate reading it is also useful to employ a dashpot, as shown in the sketch. When a test is to be made weights are placed on the scale, and the screws are tightened to such an extent that the lever keeps, as it were, floating midway between the two stops, and opposite a fixed mark. If the lever has a tendency to rise weights must be added or the screws slackened, if it has a tendency to fall weights must be taken off, or the screws must be tightened. To prevent fraud by the attendant, who manipulates the handles *h h*, and who can by putting undue pressure with his hands on one or the other side of the shaft alter the reading, the top nuts are sometimes worked from a distance by universal couplings and sliding sleeves.

(TO BE CONTINUED).

---

## ON THE ELECTROMOTIVE FORCE OF A DANIELL CELL IN ELECTRO-STATIC MEASURE, AND THE DETERMINATION OF THE RATIO BETWEEN THE ELECTRO-STATIC AND ELECTRO-MAGNETIC UNITS.*

BY PROFESSOR FRANZ EXNER.

Sir W. Thomson has obtained the value of 0·00296 for the electromotive force of a Daniell cell expressed in electro-static units, and in a later research the value 0·00374. The discrepancy between these numbers has led the author to make a new determination by a direct method. One plate of a condenser placed horizontally was fixed; above it a smaller plate was suspended by three platinum wires attached to the end of one arm of a balance. The upper plate was surrounded by a guard-ring of the same diameter as the lower plate, and the distance between the plates could be regulated and measured by a micrometer screw. The under plate was first insulated, and the guard-ring put to earth; the former was then coupled to the battery whose electromotive force was to be measured, and the weight observed necessary to bring the upper plate back to its original position, special precautions being taken to ensure that the plates were then parallel, and the lower surface of the upper plate in the same plane as the surface of the guard-ring. If V be the difference of potential between the plates, *d* their distance, S the area of the upper plate, and *mg* the counter-balancing weight, the gram, centimetre, and second being taken as units, then

$$V = d\sqrt{\frac{8\pi m g}{S}}$$

in electro-static measure.

The battery employed consisted of four hundred small Smee elements, which remain perfectly constant, provided they are kept on open circuit, and can be readily compared with a Daniell cell. The vibrations of the balance were limited by a fork placed over one arm in such a way that, the pan being loaded with a given weight, the pointer of the balance coincided with zero of scale. The number of cells in the Smee battery was then varied by changing the earth connection, until the electrical attraction balanced the weight. In this way the distance between the condenser plates re-

* Abstract from Exner's "Repertorium der Physik," Vol. XIX., 1883, p. 99, published in "Abstracts of Papers in Foreign Transactions, &c.," issued by the Institution of Civil Engineers.

Digitized by Google

mained the same throughout the experiment. The upper plate had a diameter of 73·9 millimetres, and the guard-ring an inner and outer diameter of 75·5 and 197 millimetres respectively. The electromotive force of the Daniell element being deduced from that of the Smee battery by direct comparison by means of one of Thomson's absolute electrometers, the results of a great number of observations for different distances of the plates, from 0·545 millimetre to 2·186 millimetres, varied from 0·00310 to 0·00334. It was found necessary that the distance between the plates should exceed one millimetre, to prevent sparking from one plate to the other, and consequent polarisation of the battery. Taking the mean of the results, the electromotive force of a Daniell in electrostatic units is 0·00325.

The author used the same Daniell elements for the determination of the ratio of the electro-static and electro-magnetic units. The amount of copper deposited by an element in a known time and through a known resistance was measured, and the electromotive force of the element deduced therefrom. Assuming the chemical equivalent of copper to be 0·00324, and a Siemens unit as 971,700,000 absolute units, the mean value of the electromotive force obtained for several elements was 0·978 volt, whence $v$, the ratio of the units, is $3·01 \cdot 10^{10}$. The values for $v$ found by other experimenters are as follow:—

| | | |
|---|---|---|
| W. Thomson | 2·82 | $0·10^{10}$ |
| Maxwell | 2·88 | |
| Stoletow | 2·99 | |
| Shida | 3·00 | |
| Klemencic | 3·04 | |
| Weber and Kohlrausch | 3·11 | |

It will be observed that the Daniell cell employed had an electromotive force about 10 per cent. less than that of the normal Daniell. This may be accounted for by the different construction of the cell, the two fluids being separated by an earthenware diaphragm instead of by capillary tubes, as in the normal element. After comparing the two elements by means of an electrometer, the values obtained for the electromotive force reduced to the normal element are 0·00357 in electrostatic measure, and $1·076 \cdot 10^8$ in electro-magnetic measure.

The author concludes the paper with an account of two experiments on the dependence of the electromotive force of electrostatic machines on the velocity of rotation. The first machine tried was a Holtz induction machine, with plates 35 centimetres in diameter. For one revolution per second the electromotive force was 9,540 Daniells, but for 3·5 revolutions per second 20,580 Daniells. With a Winter friction machine, having discs 43 centimetres in diameter, the electromotive force appeared to be independent of the velocity of rotation, and amounted to 11,610 Daniells.

## ON SECONDARY BATTERIES AND THE ELECTRICAL STORAGE OF ENERGY.*

BY PROFESSOR OLIVER LODGE, M.A., D.SC.

*Lecture I.—Monday, May 21st*, 1883.

The ordinary methods of storing energy at present in use may be divided roughly into mechanical, chemical, and electrical. As an example of the first kind, we may take the raising of weights, which is accomplished on a large scale hydraulically, and is applied to the working of cranes and dock gates; another example is the coiling of springs, as in clocks and musical boxes. An example of a chemical store of energy is gunpowder; another is zinc or other smelted metal; and a third example is vegetation, whence arises all the energy of coal and gas engines. The charging of a Leyden jar, and the decomposition of dilute acid, furnish examples of electrical storage, and the explosive gases derived from the last-mentioned operation could doubtless be used to drive some form of gas-engine.

All these methods of storing energy involve some loss, and many of them are accompanied with a great deal of loss. The advantage of being able to store energy frequently outweighs the disadvantage of a considerable amount of loss of energy in the process; and there are three main cases in which this occurs.

One is when regularity and continuity of supply of energy is needed, and when the source of energy to be utilised is irregular and fitful. For instance, it would be convenient to be able to store wind or wave power, and utilise it in an equable and dependable manner.

Another case is when occasional power is needed at times when the source of energy is not acting, or when a very great power is required for a short time, whereas the source of energy at your command has a steady but insufficient power. This would be exemplified in the utilisation of a small engine for lighting purposes.

The third case is when the power at your disposal is so great and so unutilised that the saving of even a fraction of it is a clear gain, no matter what becomes of the rest. This case frequently occurs when natural water power is utilised. Processes of vegetation also utilise but a meagre proportion of the solar radiation, but the small proportion saved and stored up in the coal fields represents so much clear gain.

The mode of electric storage which has recently excited so much interest involves the use of a secondary battery, which may be defined as an instrument for receiving the energy of an electric current, and for giving it out again in the same form. This is a case of storage without transmutation, such as is also accomplished in the simple operation of winding a clock, where mechanical energy is taken in, to be subsequently given out in the same form. But in the electro-chemical decomposition of acid, the energy of an electric current is stored in such a way as to give sound, and heat, and light, and motion, but not an electric current under ordinary circumstances. There is one arrangement for making the evolved gases directly furnish an electric current, and that is a true secondary battery, viz., Grove's gas battery, or a voltameter.

A primary battery means one in which the plates have been made, or prepared and rendered active, by chemical means; a secondary battery means one in which the activity of the plates depends upon electrical energy having been first expended upon them. Any two conducting bodies, immersed in a conducting liquid able to chemically attack one of them more than the other, constitute a battery; and the difference in the attackability of the two bodies or "plates" may be caused either by making them originally of different materials, or else by modifying their surfaces in some way, permitting the main bulk of them to remain identical.

Most run-down batteries can be re-excited by forcing a reverse current through them, and they then become true secondary batteries.

The polarisation of voltameter plates was studied by Gautherot, Ritter, and Grove, in the earlier years of the century; and more recently and exhaustively by Planté, who found that plates of lead acted extremely well, and retained their energy for a long time.

The gas battery consists of two similar platinum plates, one soaked, or coated, or alloyed, with hydrogen, the other with oxygen. But the quantity of oxygen which platinum can store up is very minute; the advantage of using a metal actually oxidisable is manifest. Platinum, and still more palladium, have considerable holding power for hydrogen, but by the use of a salt or an oxide as a recipient of the hydrogen, a far greater amount of reversible action can be stored up than by attempting to store up the hydrogen itself by any power of occlusion.

A Planté cell, from the beginning, furnishes an oxidisable plate on the positive side, but its negative plate has at first no practical occluding power for hydrogen.

Reversing a once charged Planté cell, however, we get metallic lead for the oxidisable plate, and an already oxidised, and therefore reducible, plate to receive the hydrogen; the oxide gradually being reduced to metallic lead, of a porous or spongy consistency. By many reversals of this kind, Planté "formed" his cells, until the lead plates were deeply acted on, and a considerable storage capacity obtained.

The modification of Faure consisted in providing both an oxidisable and a reducible porous material from the very first, by coating the plates with minium or litharge. The plates could then be peroxidised, and reduced respectively to a considerable depth, without any tedious process of "formation." A considerable storage capacity was thus obtained, but difficulties presented themselves connected with the adhesion of the coatings to the plates, and these were not got over until perforated plates were employed to hold the applied substances. Perforated plates, by rendering unnecessary any jacket of cloth or felt to keep the coating on, and by thus permitting a free circulation of the liquid, no doubt are a considerable improvement; and cells, as now made, often work extremely well. At the same time a layer of uniform thickness spread all over the plate, and not locally distributed in a non-homogeneous manner, would seem theoretically to be preferable, if the practical difficulties connected with such a uniformly spread layer had not seemed too great. Plates made in the old manner did not safely bear transport and

* Cantor Lectures. Reprinted from the *Journal of the Society of Arts*.

Digitized by Google

rough usage, and a film of insulating sulphate of lead was apt sometimes to creep between the metallic lead and the peroxide coating, and to destroy all electrical connection between them over large patches.

The process of manufacture, as now carried on, is here illustrated by a number of specimens of plates in different stages, kindly lent for the purpose by the Electrical Power Company, of Millwall.

The first operation is the casting of the lead grid, the holes in the plate being from $\frac{1}{4}$in. to $\frac{3}{8}$in. square. The positive grid is made a little thicker than that which is to be the negative, for reasons which will shortly appear. The thickness of the grids at present most employed are, positive, $\frac{1}{4}$in. to $\frac{5}{16}$in.; negative, $\frac{1}{16}$in. to $\frac{1}{8}$in., and they are made in two sizes, one $7\frac{1}{4}$in. by $5\frac{1}{4}$in., the other 9in. by 10in.; the former being used in the small or "half horse-power" boxes, the larger plate being used in all other sizes, it being found more convenient to vary the number of plates in a cell than to have in stock a number of different sized plates. The weights of the formed plates are, small size negative, 15oz., small size positive 21oz.; large size negative, 50oz., large size positive, 70oz., about.

The next operation is the filling of the grids with a paste of oxide of lead mixed with dilute sulphuric acid. The negative plates are filled with litharge, PbO, the positive with minium, $Pb_3O_4$, since there is an evident economy in having to reduce only the lower oxide, and to peroxidise only the higher one.

The plates are then taken to be "formed" by the electric current, for which purpose they are packed alternately in square stoneware jars filled up with dilute sulphuric acid, and a current of about two or three amperes per pair of plates supplied. At the instant of immersion in acid, a darkening of the minium occurred, owing to a partial formation of peroxide in it by the action of the acid; and this darkening continues, under the influence of the nascent oxygen liberated by the current, until the whole of the composition is converted into peroxide. The litharge is, on the other hand, gradually reduced to metallic lead by the action of the nascent hydrogen produced by the current, the reduced lead having a slightly porous or spongy consistency.

No gas is evolved from the cells for some time; it is all consumed in effecting these chemical changes. A few minute oxygen bubbles do, however, make their appearance on the positive plate, much of it being in the form of ozone. Ultimately, as the surface of the positive plate gets peroxidised over, a good deal of oxygen escapes, and it is only after a long-continued current that the portions of minium in the interior get acted upon. In time all the minium is attacked, however deeply buried; the reason being that less E.M.F. is needed to send the current to an oxidisable substance than to saturated peroxide. The reduction of the litharge is a somewhat slower process, but the plates being thinner, it is accomplished in approximately the same time, which may be taken as between three days and a week. When the process is approaching completion, torrents of both kinds of gas rise from their respective plates. The plates are then removed from the forming pot, rinsed plentifully with water to remove the excess of acid, and then stacked till wanted. Unless the rinsing operation is carried out, the spongy lead plates are found to heat considerably, by reason of the acid in their pores combining with the lead.

In order to keep the plates from touching each other when subsequently used in battery cells, various devices have been tried. The one now most in favour is to punch out the composition from a tolerable number of the holes of each negative plate, and to insert instead a block of vulcanised india rubber in each. These plugs project nearly a quarter of an inch on either side the face of the plate, and effectually prevent the adjacent positive from coming into contact with it.

Another matter which has given some trouble to determine is the best method of connecting the plates together. All the positive and all the negative plates in a cell have to be electrically connected in the most complete and permanent manner. Clips and clamps of various kinds have been tried; but, to guard against all possibility of corroded surfaces and imperfect connection, it is now thought wise always to use solder, whether in combination with screw clamps, or otherwise, and to protect the joint from the action of acid spray by a varnish, or by a mass of paraffin. It is curious to notice how persistently the junction of the + plates tends to corrode, showing how the oxidising action creeps up liquid films on the lugs.

When the plates are to be used, they are packed alternately in glass or ebonite boxes, the india-rubber plugs keeping them apart, and wooden supports keeping them off the bottom of the cell. Their lugs are connected together, and the box is filled with dilute sulphuric acid, say, of specific gravity 1·100 or 1·150. A charging current is then supplied, so as to freshen up the plates, and they are then discharged, and charged up again once or twice, to bring them into good condition. It is not a good plan to discharge them too completely, nor to let them remain idle for very long together; neither should they be charged or discharged too rapidly, so as to heat them above a gentle warmth. The more regularly they are worked—as, for instance, when they receive a charge every day and discharge every evening—the better they behave. Regularly and carefully worked cells will keep good in order for a very long time; but if they remain idle for weeks together, some of the plates are apt to warp, and otherwise give trouble and require attention. They must not be overcharged very excessively either. When full, they indicate the fact by evolving a good deal of gas, and it is best not to continue the charging power much longer when this stage is fully reached, partly because nearly all the charge then put in is wasted, but principally because a little of the oxygen is absorbed by the lead of the grid, and it therefore gets slowly peroxidised, so that, after a sufficient lapse of time, it may get actually eaten through, and the plate become friable. When a plate has got into this state, the only plan seems to be to melt it down with a flux, and recover the lead. But the complete peroxidation of a plate by overcharging is a work of time, by far the greater quantity of gas being harmlessly, though wastefully, set free; and it is not necessary to be alarmed at a slight evolution of gas which usually goes on from the positive plate when being charged, more especially as the cell is getting full. Alarm at the appearance of bubbles may lead to the cell never being properly filled up, in which case the battery will fail to work satisfactorily.

The number of plates which are packed into each box depends entirely upon the size of the box, and it is in this way that the different sized cells are constructed, not by varying the size of the plates, except that the smallest cells are made with half-sized plates.

Taking the full-sized plates, we may reckon that each pair is able easily to receive and give out electricity at the rate of 4 amperes per pair. This, of course, reckons both faces of each plate as active. This process may be continued for, say, 8 hours on the average, consequently the storage capacity of a cell is 32 ampere hours per pair of plates. The E.M.F. of discharge is as nearly as possible 2 volts; consequently the power of a cell is 8 watts per pair of plates; and the total available energy per pair of plates, when full, is 8 watts for 8 hours, or 170,000 foot-pounds, which may be also, though clumsily, expressed as 1-12th of a horse-power-hour per pair of plates. Consequently, a box which is to give 1 horse-power-hour should contain 12 pair of plates; a 2 horse-power box 24 pair, and so on. But each box will not really give a horse-power for an hour, it will rather give an eighth of a horse-power for 8 hours. If a horse-power is wanted, all you need do is to take 8 cells, and then they will give you a horse-power and will last 8 hours; 16 cells will give 2 horse-power for the same time, and so on. By drawing off the power more slowly the discharge will last longer, and it is more economical thus to work, except as regards first cost of batteries. This latter item it is which usually causes them to be called upon to exert power up to their maximum reasonable capacity. It is true that a cell will give a much higher power for a short time if called upon—thus a single cell might possibly be made to give a horse-power, but then it would not last out its proportionate time. I have found some cells which I discharged at a very moderate rate continue discharging an extraordinary time, and give out sometimes even more than was put in, which, of course, means that the effect of previous charges was being drawn upon.

When a cell which is being rapidly discharged has apparently run completely down, a few minutes' rest will suffice to recover it a little; and after an hour or two's rest a cell will commonly have recovered sufficiently to enable it to discharge with something of its old vigour for a period comparable with that of the rest. This recuperative power of the cells is in some respects advantageous, but, on the whole, it would be better if they gave out the whole of their energy continuously without needing intervals for refreshment. The more slowly a cell is discharged the less noticeable is this temporary falling off and subsequent recovery.

When a cell has run down it is interesting to examine which of its three constituents is the one that has failed—the positive plate, the negative plate, or the acid. Sometimes, especially in cells too crowded with plates, there is not enough acid present; the free acid is absorbed by the lead, and only water is left. The specific gravity of the acid may, however, be easily watched by floating a little hydrometer in the cell. More frequently the negative plate is the first to fall off, as may be shown by removing it and inserting a fresh one, when the cell will go on again. The cause of this, and of several other peculiarities observed in batteries, may be readily made out by experiments on a small scale, on two little plain lead strips, held in a convenient clamp, and immersed in dilute acid.

To a pair of such strips of sheet lead supply a current, from a couple of Groves say, for half an hour or so. The positive

Digitized by Google

plate is seen to become coated with a puce layer, which gradually darkens to black. The other plate seems unchanged. Gas is evolved from both plates. On now connecting them with an electric bell it will ring for a minute or more. Now re-charge, but this time, instead of discharging the cell, remove the negative plate, and insert instead a bit of clean lead, the same in appearance as the one against which hydrogen has been so long liberated, and then discharge the cell; it will only ring the bell for about two seconds. Depress the plain lead plate further into the acid, so as to expose a fresh surface, and the bell will give a few more strokes. Remove this plate altogether, and re-insert the hydrogenised plate which had been used for charging the cell, and the bell rings vigorously for as long a time as it did in the first experiment, showing that the peroxide plate is perfectly vigorous, and showing also that the nascent hydrogen has modified the lead in some way or other.

The natural supposition is that the lead has occluded hydrogen, but Dr. Frankland has shown that, if such hydrogenised lead be melted down, it gives off no hydrogen worth mentioning. It is not easy to see wherein the change consists. Under the microscope, the hydrogenised plate looks a little darker than the plain plate, but no real porosity is noticeable. The fact, however, is certain that it behaves in a very different manner to plain lead, and that it retains this singular power long after it has been removed from the liquid and rinsed.

To avoid misunderstanding, it might have been well to state earlier that I use the term "positive plate" to signify that at which the charging current enters, and from which the discharge current leaves. It is that one whose terminal is coloured red in the cells of commerce. It is that which must be joined to the + pole of a magneto-machine, whether the latter is to act as a generator or a motor. I make no distinction between positive plate and positive pole, because all such distinctions end in confusion.

The plain lead plate which refused to give a current when opposed to peroxide did not fail because of its high position in the electro-chemical series, as may be proved by opposing it to the hydrogenised plate, when it is equally inert; it fails simply and solely on account of a film of some non-conducting substance which spreads over its surface the instant it is used as one electrode of a battery, the substance appearing to be sulphate of lead. The internal resistance of the cell thus becomes enormous, and the current ceases. On standing idle for a time, the film has a chance of clearing off—though from a plain lead plate I do not notice much tendency to clear—or it may be wiped off with a cloth at once; but a fresh film speedily forms. If amalgamated lead be used, the white scum can be seen, and it sometimes drops off in a filmy sheet. One remarkable way of instantly clearing off the scum is to touch the lead under the liquid with a scrap of amalgamated zinc. The effect is magical; the scum vanishes, and the bell again rings for several seconds after the zinc has been removed. So long as the zinc is present the current will continue, until indeed the positive plate becomes exhausted.

To examine whether the positive plate also exhibits the temporary falling off, and to eliminate the concurrent action of the negative, the best plan is to use a piece of amalgamated zinc for the latter; for since sulphate of zinc is soluble, it remains perfectly clear, and all variation is traceable at once to the behaviour of the positive. Under these circumstances, the cell, if rapidly discharged, does show a slight recuperative power, recovering somewhat on standing. So far as I can make out, this appears to be mainly due to a temporary exhaustion of the acid close to the surface and in the pores of the peroxide, so that the power falls until, by rapid diffusion, the absolved acid has been replenished. The insulating scum of sulphate on the negative plate is, however, by far the most powerful cause of the ordinary running down of a cell.

When we come to try the hydrogenised plate employed in charging the cell instead of the plain plate, we find that it also ceases to act before the positive is exhausted, though it is able to go on for a considerable time; it ultimately acquires a scum. On standing, the scum clears off partially, and the cell recovers. A piece of zinc made to touch the plate under the liquid clears it, and in a short time restores it to its original power, having precisely the same effect as a re-application of the charging current. The fact is not surprising, since the zinc naturally causes nascent hydrogen to be liberated on the plate, just the same as a current would; but the quick and prompt action of the merest scrap of zinc is somewhat striking, and some practical application of the fact would seem to be possible.

Instead of a plain lead plate, lead sponge may be employed for the negative plate, such as is made by Watt, of Liverpool, by blowing high pressure steam through a jet of molten lead, or such as Mr. Desmond FitzGerald has brought me here, made in some other way. The enormous surface of this spongy lead enables it to go on acting for a much longer time than plain lead, without being stopped appreciably by a scum. This effect is due to the extent of surface, and it appears to be owing to a sort of potential hydrogenation caused by the ability of acid to attack spongy lead, or any metal in a fine state of division, more easily than when massive; and the sulphate of lead formed, though it certainly clogs up the pores, is not readily able to form a continuous protecting film.

A thin coat of peroxide formed on a lead plate rapidly becomes lighter in colour when the current is stopped, being evidently reduced to a lower oxide by local action with the lead underneath. When the coat is very thin, the changes go on so rapidly that, by quickly pressing the charging battery key down and up, flashes of peroxide appear and disappear on the surface. It is by this local action effect, no doubt, that peroxidation eats deeper and deeper into metallic lead, for otherwise, as soon as a complete layer of peroxide was once formed, all subsequent gas would be given off from its surface (it being a conductor), and the lead beneath would be protected.

The local action proclivity between lead and peroxide has two unpleasant consequences, however; one is that the peroxide gradually disappears on long standing, and the cell thus loses its charge; the other is that the metallic lead of the plate gets gradually eaten into, and corroded away. These two results are modified in practice by the fact that, whereas local action destroys the peroxidation of thin films in an instant, in the deeper layers of thick films it goes on very slowly, partly because fresh acid cannot so easily penetrate, but principally because the sulphate and lower oxides formed, being non-conductors, exert a clogging and protective action.

Instead of using a lead negative plate, a copper plate may be used, and will give strong and lasting current. It lasts, of course, because copper sulphate is soluble, and no insulating scum is formed; but that this Sutton cell has a fairly high E.M.F. is a striking proof of the value of peroxide of lead as the electro-negative element of a battery.

Even platinum gives a current when opposed to peroxide of lead, though of course it is a feeble one. But if zinc is used, we have the strongest practicable battery I know, each cell having an E.M.F. of 2½ volts.

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 598).

### CHAPTER V.—TELEGRAPHS (CHEMICAL) BASED ON DYNAMIC ELECTRICITY.

Awhile forbear,
* * * * * *
Nor scorn man's efforts at a natural growth,
Which in some distant age may hope to find
Maturity, if not perfection.
*Household Words*, June 14, 1851.

#### 1800-4:—SALVÁ'S TELEGRAPH.

It is generally supposed that Sömmerring was the first to employ the electricity of the pile for telegraphic purposes; but M. Saavedra† has shown that this honour belongs to his distinguished countryman, Don Francisco Salvá, whose name has already occurred in our pages (*The Electrician*, August 25, 1883, pp. 346-7).

At a meeting of the Academy of Sciences of Barcelona, held on the 14th May, 1800, Salvá read a paper, entitled "Galvanism and its application to Telegraphy," in which, after an elaborate dissertation on the phenomena and theories of the new science, he proceeds to consider its application to telegraphy. He relates the experiments made for this purpose at his residence with line wires, some 310 metres long, stretched across the terrace and garden, and fastened at the ends to varnished glass insulators, and through which he distinctly perceived the convulsions of the frog, notwithstanding the distance. The fact that the contractions sometimes took place without closing the circuit led to the discovery, that, on account of the wire being uncovered, its extension permitted its taking electricity from the atmosphere, so as to act upon the frog. The insulated wires, adds Salvá, can act by means of galvanism alone, as he demonstrated by insulating his small line. He expressed the conviction that he could obtain a telegraphic communication at a much greater distance.

The memoir does not enter into details as to this new Tele-

graphic proposal, limiting itself to saying that it could be made by a process analogous to that described at the meeting of December 16, 1795,* with the advantages of greater durability and cheapness as compared with the old plan.

Salvá employed, as his motive power, the electricity produced by a great number of frogs.

This illustrious Spanish physician was therefore the first person who attempted to apply electricity dynamically for the purpose of telegraphing. It is, says Saavedra, not without reason I must confess, notwithstanding my cosmopolitan opinions in scientific questions, that the Catalans hold Salvá to be the inventor of electric telegraphy. With documents as authentic as those which I have seen with my own eyes, in the very handwriting of this distinguished professor, which documents are at this present moment to be found in the library of the Academy of Sciences of Barcelona, it is impossible for any author to henceforth deny, even if others did precede Salvá in telegraphic experiments with static electricity, that no one preceded him in the application of the docile electro-dynamic fluid to distant communications.

On the 22nd February, 1804, when the invention of the voltaic pile had hardly begun to be known in Europe (for in that period there were no telegraphs or railroads), Don Francisco Salvá Campillo read before the Academy of Sciences at Barcelona another paper, called "The Second Treatise on Galvanism applied to Telegraphy." He therein enumerates the difficulties which optic telegraphy presents in actual practice, and shows its inadequacy to the amount of work required, and its unproductiveness to the State, on account of the great expense attending its erection and maintenance. He relates, referring to two personal friends as witnesses, that Napoleon I., in the midst of a Session of the National Institute of Paris, declared that he had often received news by mail sooner than by the optic telegraph, which is not to be wondered at, considering the fogs and other impediments peculiar to that system.

Salvá says in this paper, that when he read the previous one in 1800, he had not heard of the instrument invented by Volta, called *Volta's Column*, which is not strange, considering its so recent invention, and that it was not made public at all until the middle of the year 1800, when it was published in Nicholson's *Journal*. This, says Salvá, yields more fluid than the electric machine, and could be well applied to telegraphy, as the force can be obtained more simply and steadier than in the static form. He describes what had been done by scientific men towards improving its form. He observes that the force of the shock is in proportion to the number of pairs, but not to the extent of surface in contact, and relates the experiments made to demonstrate this. He proposes to avoid the excessive height of the pile (the well-known objection to which is the great weight of the upper discs pressing on those below), by forming a battery of several piles united. He complains of its being so difficult to clean, and expresses his belief in the eventual obtainment of analogous piles in a much greater state of perfection.

As to the means of indicating the signals Salvá shows some hesitation, since, although he alludes to the contractions of frogs as adequate to the effect, he manifests an inclination for employing the decomposition of water.

For this last he gives sufficient explanation as to the system that could be adopted. It would suffice for the ends of each pair of wires to be inserted through a cork into a glass tube containing water. As the wire that communicates with the zinc plate of the pile is covered with bubbles of hydrogen gas, and the silver one is oxydated, this would economise, in the diversity of their effects, one half the conductors, since in applying the wires corresponding to a pair in a certain way to the poles of the voltaic pile, the letter A, for example, could be had, and, effecting the contact in a contrary way, the letter B could be indicated. Six wires would thus be enough for a telegraph, which would greatly reduce the expense and simplify the installation. After reading this paper Salvá proceeded to the experiments necessary towards perfectly understanding the above statements.

The apparatus constructed by Salvá on this occasion has not been preserved, but from the description of it in the memoir M. Saavedra thinks that it took a form similar to that shown in figure (1). On a table was arranged a number of flasks of water, one flask serving for two letters, or signals. Into each dipped two metallic rods, one of which was connected to a corresponding line wire, and the other to a return wire, of which there was only one, common to all. The different line wires and the return wire were similarly connected at the distant end.

When it was desired to transmit a signal all the line wire rods at the sending end were removed from the flasks, or raised so as to be clear of the water, then one pole, say the positive, of a pile was touched to the return wire, and the other pole, the negative, to the wire corresponding to the letter desired to be signalled. Immediately this was done the water in the flask, into which the distant ends of the wires dipped, began to be decomposed, bubbles of oxygen gas being given off at one rod, and bubbles of hydrogen at the other. By reversing the poles of the pile at the sending end the bubbles of oxygen and hydrogen changed places, thus making it possible for one wire to serve for two signals, for since the bubbles of hydrogen (being the more numerous) were taken to represent the signals, their evolution at the line wire might stand for the letter A, and at the return wire for B, and so on. When the communication was ended the rods were let down into the water, and the distant correspondent proceeded in the same manner to transmit his reply.

These notable and interesting memoirs, says Saavedra, have, ever since they were read, slept the sleep of the innocent on the shelves of the modest Scientific Academy of Catalonia; no one took the trouble to publish them at the time—a thing not strange in those days when their transcendent value was not appreciated, and when scientific journals were few in number, and little given to investigation; but it was unpardonable to neglect their publication, subsequently, when the glorious realisation of public telegraphy excited general enthusiasm, and all the civilised nations made every effort to allege—through their numerous scientific and literary publications—the part each had taken in the great discovery. If, therefore, neither the author, nor any

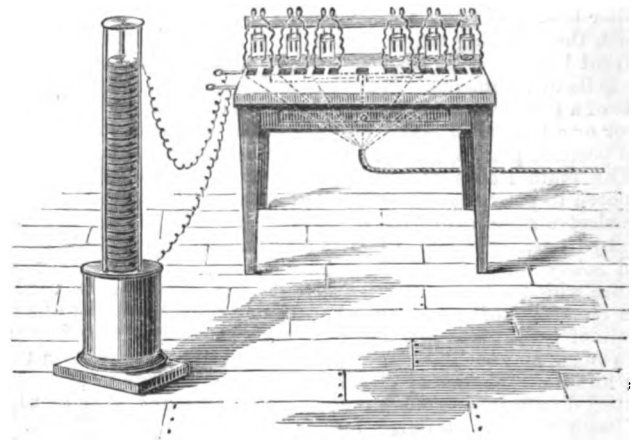

FIG. 1.—Salvá's Telegraph.

one else in Barcelona, or even in Spain, took the trouble to publish these trials of an electric telegraph, is it to be wondered at that foreign authors do not mention them, attributing to Sömmerring and to Coxe of 1809 and 1816 the first application of voltaic electricity to telegraphy? Is it strange that this should be the case when even the few Spanish writers who pay any attention to these matters, repeat the same words in chorus, as though the unfortunate country of Cervantes and Balmes were not also the birth-place of Blasco de Garay and of Salvá?

In this connection we would ask our readers to peruse again our former article on Salvá, which will be found at page 346 of this journal for August 25.

We join with M. Saavedra in the hope that his distinguished countryman will in future be better known and appreciated for his early and valuable contributions to the art of telegraphy.

## VOLTA-ELECTRIC INDUCTION.*

BY WILLOUGHBY SMITH.

In my presidential address which I had the pleasure of reading before this society at our first meeting this year, I called attention, somewhat hurriedly, to the results of a few of my experiments on induction, and at the same time expressed a hope that at a future date I might be able to bring them more prominently before you. That date has now arrived, and my endeavour this evening will be to demonstrate to you by actual experiment some of what I consider the most important results obtained. My desire is that all present should see these results, and with that view I will try when practicable to use a mirror reflecting galvanometer instead of a telephone. All who have been accustomed to the use of reflecting galvanometers will readily understand the difficulty, on account of its delicacy, of doing so where no special arrangements are provided for its use; but perhaps with a little indulgence on your part and patience on mine the experiments may be brought to a successful issue.

Reliable records extending over hundreds of years show clearly with what energy and perseverance scientific men in every civilised part of the world have endeavoured to wrest from nature the secret of what is termed

* A Paper read at the Society of Telegraph Engineers and Electricians on the 8th November, 1883.

Digitized by Google

her "phenomena of magnetism;" and, as is invariably the case under similar circumstances, the results of the experiments and reasoning of some have far surpassed those of others in advancing our knowledge. For instance, the experimental philosophers in many branches of science were groping as it were in darkness until the brilliant light of Newton's genius illumined their path. Although perhaps I should not be justified in comparing Oersted with Newton, yet he also discovered what are termed "new" laws of nature, in a manner at once precise, profound, and amazing, and which opened a new field of research to many of the most distinguished philosophers of that time, who were soon engaged in experimenting in the same direction, and from whose investigations arose a new science, which was called "Electro-dynamics." Oersted demonstrated from inductive reasoning that every conductor of electricity possessed all the known properties of a magnet while a current of electricity was passing through it. If you earnestly contemplate the important adjuncts to applied science which have sprung from that apparently simple fact, you will not fail to see the importance of the discovery; for it was while working in this new field of electro-magnetism that Sturgeon made the first electro-magnet, and Faraday many of his discoveries relating to induction.

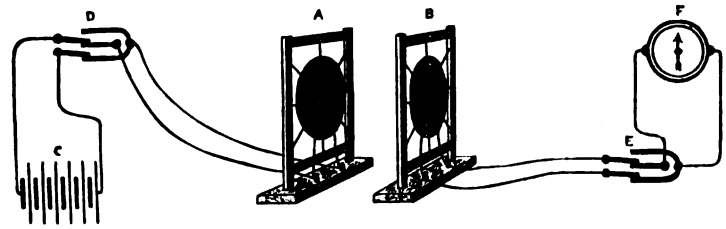
Soon after the discovery by Oersted just referred to, Faraday, with the care and ability manifest in all his experiments, showed that when an intermittent current of electricity is passing along a wire it induces a current in any wire forming a complete circuit and placed parallel to it, and that if the two wires were made into two helices and placed parallel to each other the effect was more marked. This Faraday designated "Volta-electric-induction," and it is with this kind of induction I wish to engage your attention this evening; for it is a phenomenon which presents some of the most interesting and important facts in electrical science.

Here are two flat spirals of silk-covered copper wire suspended separately, spider-web fashion, in wooden frames marked respectively A and B. The one marked A is so connected that reversals at any desired speed per minute from a battery of one or more cells can be passed through it. The one marked B is so connected to the galvanometer and a reverser as to show the deflection caused by the induced currents, which are momentary in duration, and in the galvanometer circuit all on the same side of zero, for as the battery current on making contact produces an induced current in the reverse direction to itself, but in the same direction on breaking the contact, of course the one would neutralise the other, and the galvanometer would not be affected; the galvanometer connections are therefore reversed with each reversal of the battery current, and by that means the induced currents are, as you perceive, all in the same direction and produce a steady deflection. The connections are as shown on the sheet before you marked 1, which I think requires no further explanation.

Before proceeding please to bear in mind the fact, that the inductive effects vary inversely as the square of the distance between the two spirals, when parallel to each other; and that the induced current in B is proportional to the number of reversals of the battery current passing through spiral A, and also to the strength of the current so passing.

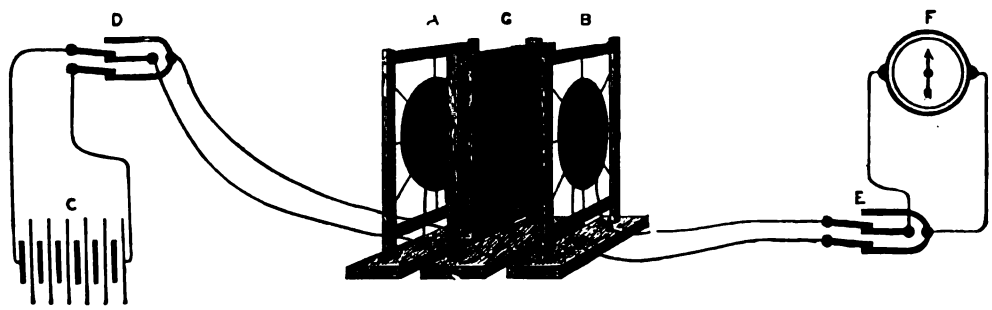
Faraday's fertile imagination would naturally suggest the question, "Is this lateral action, which we call magnetism, extended to a distance by the action of intermediate particles?" If so, then it is reasonable to expect that all substances would not be affected in the same way, and therefore different results would be obtained if different media were interposed between the inductor and what I will merely call for distinction the inductometer.

PLATE 1.



With a view to proving this experimentally, Faraday constructed three flat helices and placed them parallel to each other a convenient distance apart. The middle helix was so arranged that a voltaic current could be sent through it at pleasure. A differential galvanometer was connected with the other helices in such a manner that when a voltaic current was sent through the middle helix its inductive action on the lateral helices should cause currents in them, having contrary directions in the coils of the galvanometer. This was a very prettily arranged electric balance, and by placing plates of different substances between the inductor and one of the inductometers Faraday expected to see the balance destroyed to an extent which would be indicated by the deflection of the needle of the galvanometer. To his surprise he found it made not the least difference whether the intervening space was occupied by such insulating bodies as air, sulphur, and shellac; or such conducting bodies as copper and the other non-magnetic metals. These results, however, did not satisfy him, as he was convinced that the interposition of the non-magnetic metals, especially of copper, did have an effect, but that his apparatus was not suitable for making it visible. It is to be regretted that so sound a reasoner and so careful an experimenter had not the great advantage of the assistance of such suitable instruments for this class of research as the mirror-galvanometer and the telephone. But, although he could not practically demonstrate the effects which by him could be so clearly seen, it redounds to his credit that, as the improvement in instruments for this kind of research has advanced, the results he sought for have been found in the direction in which he predicted.

PLATE 2.

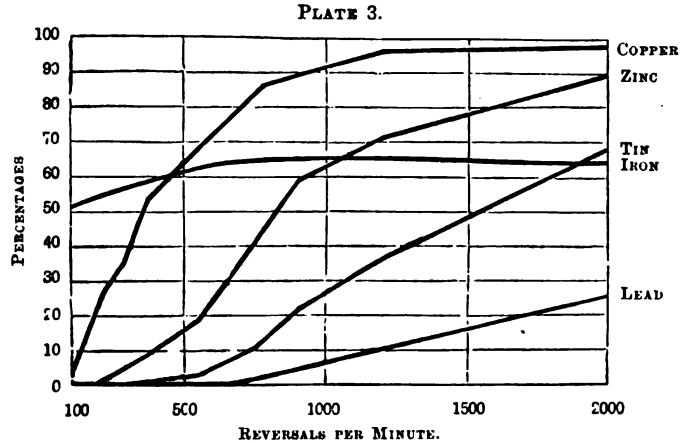


A and B will now be placed a definite distance apart, and comparatively slow reversals from ten Leclanché cells sent through spiral A; you will observe the amount of the induced current in B as shown on the scale of the galvanometer in circuit with that spiral. Now midway between the two spirals will be placed a plate of iron, as shown in Plate 2, and at once you observe the deflection of the galvanometer is reduced by less than one half, showing clearly that the presence of the iron plate is in some way influencing the previous effects. The iron will now be removed, but the spirals left in the same position as before, and by increasing the speed of the reversals you see a higher deflection is given on the galvanometer. Now, on again interposing the iron plate the deflection falls to a little less than one half as before. I wish this fact to be carefully noted.

The experiment will be repeated with a plate of copper of precisely the same dimensions as the iron plate, and you observe that, although the conditions are exactly alike in both cases, the interposition of the copper plate has apparently no effect at the present speed of the reversals, although the interposition of the iron plate under the same conditions reduced the deflection about fifty per cent. We will now remove the copper plate, as we did the iron one, and increase the speed of the reversals to the same as in the experiment with the iron, and you observe the deflection on the galvanometer is about the same as it was on that occasion. Now, by replacing the copper plate to its former position you will note how rapidly the deflection falls. We will now repeat the experiment with a plate of lead, and you will see that like the copper it is unaffected at the low speed, but there the resemblance ceases; for at the high speed it has but very slight effect. Thus these metals, iron, copper, and lead appear to differ as widely in their electrical as they do in their mechanical properties. Of course it would be impossible to obtain accurate measurements on an occasion like the present, but careful and reliable measurements have been made, the results of which are shown on the sheet before you marked 3.

It will be seen by reference to these results that the percentage of inductive energy intercepted does not increase for different speeds of the reverser in the same rate with different metals, the increase with iron being

PLATE 3.



Digitized by Google

very slight, while with tin it is comparatively enormous. It was observed that time was an important element to be taken into account while testing the above metals, that it to say, the lines of force took an appreciable time to polarise the particles of the metal placed in their path, but having accomplished this they passed more freely through it.

Now let us go more minutely into the subject by the aid of Plate IV., Figs. 1 and 2. In Fig. 1 let A and B represent two flat spirals, spiral A being connected to a battery with a key in circuit and spiral B connected to a galvanometer; then, on closing the battery circuit, an instantaneous current is induced in spiral B. If a non-magnetic metal plate half an inch thick be placed midway between the spirals, and the experiment repeated, it will be found that the induced current received by B is the same in amount as in the first case. This does not prove, as would at first appear, that the metal plate fails to intercept the inductive radiant energy; and it can scarcely be so, for if the plate is replaced by a coil of wire, it is found that induced currents are set up therein, and therefore inductive radiant energy must have been intercepted. This apparent contradiction may be explained as follows. In Fig. 2 let D represent a source of heat (a vessel of boiling water for instance) and E a sensitive thermometer receiving and measuring the radiant heat. Now, if for instance a plate of vulcanite is interposed, it cuts off and absorbs a part of the radiant heat emitted by D, and thus a fall is produced in the thermometer reading. But the vulcanite, soon becoming heated by the radiant heat cut off and absorbed by itself, radiates that heat, and causes the thermometer reading to return to about its original amount. The false impression is thus produced that the original radiated heat was unaffected by the vulcanite plate; instead of which, as a matter of fact, the vulcanite plate had cut off the radiant heat, becoming heated itself by so doing, and was consequently then the radiating body affecting the thermometer.

The effect is similar in the case of induction between the two spirals. Spiral A induces and spiral B receives the induced effect. The metal plate being then interposed cuts off and absorbs either all or part of the inductive radiant energy emitted by A. The inductive radiant energy thus cut off, however, is not lost, but is converted into electrical energy in the metal plate, thereby causing it to become, as in the case of the vulcanite in the heat experiment, a source of radiation which compensates as far as spiral B is concerned for the original inductive radiant energy cut off. The only material difference noticeable in the two experiments is that in the case of heat the time that elapses between the momentary fall in the thermometer reading (due to the interception by the vulcanite plate of the radiant heat) and the subsequent rise (due to the interposing plate, itself radiating that heat) is long enough to render the effect clearly manifest; whereas in the case of induction the time that elapses is so exceedingly short that, unless special precautions are taken, the radiant energy emitted by the metal plate is liable to be mistaken for the primary energy emitted by the inducing spiral.

The current induced in the receiving spiral by the inducing one is practically instantaneous; but on the interposition of a metal plate the induced current which, as before described, is set up by the plate itself, has a perceptible duration depending upon the nature and mass of metal thus interposed. Copper and zinc produce in this manner an induced current of greater length than metals of lower conductivity, with the exception of iron, which gives an induced current of extremely short duration. It will therefore be seen that in endeavouring to ascertain what I term the specific inductive resistance of different metals by the means described, notice must be taken of and allowance made for two points. Firstly, that the metal plate not only cuts off but itself radiates; and secondly, that the duration of the induced currents radiated by the plates varies with each different metal under experiment.

This explains the fact before pointed out that the apparent percentage of inductive radiant energy intercepted by metal plates varies with the speed of the reversals; for in the case of copper the induced current set up by such a plate has so long a duration that if the speed of the reverser is at all rapid the induced current has not time to exhaust itself before the galvanometer is reversed, and thus the current being on the opposite side of the galvanometer tends to produce a lower deflection. If the speed of the reverser be further increased the greater part of the induced current is received on the opposite terminal of the galvanometer, so that a negative result is obtained.

We know that it was the strong analogies which exist between electricity and magnetism that led experimentalists to seek for proofs that would identify them as one and the same thing, and it was the result of Professor Oersted's experiment to which I have already referred that first identified them.

Probably the time is not far distant when it will be possible to demonstrate clearly that heat and electricity are as closely allied; then, knowing the great analogies existing between heat and light, may we not find that heat, light, and electricity are modifications of the same force or property, susceptible under varying conditions of producing the phenomena now designated by those terms? For instance, friction will first produce electricity, then heat, and lastly light.

As is well known, heat and light are reflected by metals; I was therefore anxious to learn whether electricity could be reflected in the same way. In order to ascertain this, spiral B was placed in this position, which you will observe is parallel to the lines of force emitted by spiral A. In this position no induced current is set up therein, so the galvanometer is not affected; but when this plate of metal is placed at this angle it intercepts the lines of force, which cause it to radiate, and the secondary lines of force are intercepted and converted into induced currents by spiral B to the power indicated by the galvanometer. Thus the phenomenon of reflection appears to be produced in a somewhat similar manner to reflection of heat and light. The whole arrangement of this experiment is as shown on the sheet before

PLATE 4.

Digitized by Google

you numbered 5, which I need not, I think, more fully explain to you than by saying that the secondary lines of force are represented by the dotted lines.

Supported in this wooden frame marked C is a spiral similar in construction to the one marked B, but in this case the copper wire is ·044 inch in diameter, silk-covered, and consists of 365 turns, with a total length of 605 yards, its resistance is 10·2 ohms, the whole is enclosed between two thick sheets of card paper. The two ends of the spiral are attached to two terminals placed one on either side of the frame, a wire from one of the terminals is connected to one pole of a battery of 25 Leclanché cells, the other pole being connected with one terminal of a reverser, the second terminal of which is connected to the other terminal of the spiral.

Now, if this very small spiral which is in circuit with the galvanometer and a reverser be placed parallel to the centre of spiral C, a very large deflection will be seen on the galvanometer scale; this will gradually diminish as the smaller spiral is passed slowly over the face of the larger, until on nearing the edge of the latter the smaller spiral will cease to be affected by the inductive lines of force from spiral C, and consequently the galvanometer indicates no deflection. But if this smaller spiral be placed at a different angle to the larger one, it is, as you observe by the deflection of the galvanometer, again affected. This experiment is analagous to the one illustrated by diagram 6, which represents the result of an experiment made to ascertain the relative strength or capability of producing inductive effects of different parts of a straight electro-magnet.

A, Fig. 1, represents the iron core, PP the primary coil, connected at pleasure to one Grove cell, B, by means of the key K. S, a small secondary coil free to move along the primary coil while in circuit with the galvanometer G. The relative strength of any particular spot can be obtained by moving the coil S exactly over the required position. The small secondary coil is only cut at right angles when it is placed in the centre of the magnet, and as it is moved towards either pole so the lines of force cut it more and more obliquely. From this it would appear that the results obtained are not purely dependent upon the strength of that portion of the magnet over which the secondary coil is placed, but principally upon the angle at which the lines of force cut the coil so placed. It does not follow, therefore, that the centre of the magnet is its strongest part, as the results of the experiments at first sight appear to show.

It was while engaged on these experiments that I discovered that a telephone was affected when not in any way connected with the spiral, but simply placed so that the lines of force proceeding from the spiral impinged upon the iron diaphragm of the telephone. Please to bear in mind that the direction of the lines of force emitted from the spiral is such that, starting from any point on one of its faces, a circle is described extending to a similar point on the opposite side. The diameter of the circles described decreases from infinity as the points from which they start recede from the centre towards the circumference. From points near the circumference the circles or curves are very small. To illustrate this to you, the reverser now in circuit with spiral C will be replaced by a simple make and break arrangement, consisting of a small electro-magnet fixed between the prongs of a tuning-fork and so connected that the electro-magnet influences the arms of the fork, causing them to vibrate to a certain pitch. The apparatus is placed in a distant room to prevent the sound being heard here, as I wish to make it inductively audible to you. For that purpose I have here a light spiral which is in circuit with this telephone. Now, by placing the spiral in front of spiral C, the telephone reproduces the sound given out by the tuning-fork so loudly that I have no doubt all of you can hear it. Here is another spiral similar in every respect to spiral C. This is in circuit with a battery and an ordinary mechanical make and break arrangement, the sound given off by which I will now make audible to you in the same way that I did the sound of the tuning-fork. Now you hear it. I will change from the one spiral to the other several times, as I want to make you acquainted with the sounds of both, so that you will have no difficulty in distinguishing them, the one from the other.

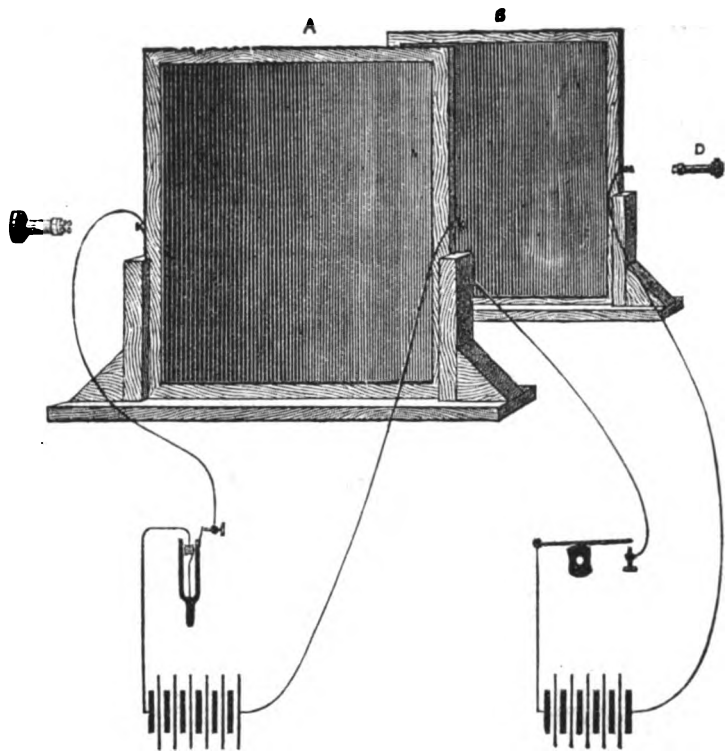
There are suspended in this room self-luminous bodies which enable us by their rays or lines of force to see the non-luminous bodies with which we are surrounded. There are also radiating in all directions from me while speaking lines of force or sound waves which affect more or less each one of you But there are also in addition to, and quite independent of, the lines of force just mentioned, magnetic lines of force which are too subtile to be recognised by human beings, consequently, figuratively, we are both blind and deaf to them. However, they can be made manifest either by their action on a suspended magnet, or on a conducting body moving across them; the former showing its results by attraction and repulsion, the latter by the production of an electric current. For instance, by connecting the small flat spiral of copper wire in direct circuit with the galvanometer, you will perceive that the slightest movement of the spiral generates a current of sufficient strength to very sensibly affect the galvanometer; and as you observe, the amplitude of the deflection depends upon the speed and direction in which the spiral is moved. We know that by moving a conductor of electricity in a magnetic field we are able to produce an electric current of sufficient intensity to produce light resembling in all its phases that of solar light; but to produce these strong currents, very powerful artificial magnetic fields have to be generated, and the conductor has to be moved therein at a great expenditure of heat energy. May not the time arrive when we shall no longer require these artificial and costly means, but have learned how to adopt those forces of nature which we now so much neglect? One ampere of current passing through an ordinary incandescent lamp will produce a light equal to ten candles, and I have shown that by simply moving this small flat spiral a current is induced in it from the earth's magnetic field equal to ·0007 ampere. With these facts before us, surely it would not be boldness to predict that a time may arrive when the energy of the wind or tide will be employed to produce from the magnetic lines of force given out by the earth's magnetism electrical currents far surpassing anything we have yet seen or of which we have heard. Therefore let us not despise the smallness of the force, but rather consider it an element of power from which might arise conditions far higher in degree, and which we might not recognise as the same as this developed in its incipient stage.

If the galvanometer be replaced by a telephone, no matter how the spiral be moved, no sound will be heard, simply because the induced currents produced consist of comparatively slow undulations, and not of sharp variations suitable for a telephone. But by placing in circuit this mechanical make and break arrangement the interruptions of the current are at once audible, and by regulating the movement of the spiral I can send signals, which, if they had been pre-arranged, might have enabled us to communicate intelligence to each other by means of the earth's magnetism. I show this experiment more with a view to illustrate the fact that for experiments on induction both instruments are necessary, as each makes manifest those currents adapted to itself.

The lines of force of light, heat, and sound can be artificially produced and intensified, and the more intense they are the more we perceive their effects on our eyes, ears, or bodies. But it is not so with the lines of magnetic force, for it matters not how much their power is increased they appear in no way to affect us. Their presence can, however, be made manifest to our eyes or ears by mechanical appliances. I have already shown you how this can be done by means of either a galvanometer or a telephone in circuit with a spiral wire.

I have already stated that while engaged in these experiments I found that as far as the telephone was concerned it was immaterial whether it

PLATE 7.



Digitized by Google

was in circuit with a spiral or not, as in either case it accurately reproduced the same sounds; therefore, much in the same way as lenses assist the sight or tubes the hearing, so does the telephone make manifest the lines of intermittent inductive energy. This was quite a new phenomenon to me, and on further investigation of the subject I found that it was not necessary to have even a telephone, for by simply holding a piece of iron to my ear and placing it close to the centre of the spiral I could distinctly hear the same sounds as with the telephone, although not so loud. The intensity of the sound was greatly increased when the iron was placed in a magnetic field. Here is a small disc of iron similar to those used in telephones, firmly secured in this brass frame; this is a small permanent bar magnet, the marked end of which is fixed very closely to, but not touching, the centre of the iron disc. Now, by applying the disc to my ear I can hear the same sounds that were audible to all of you when the telephone in circuit with a small spiral was placed in front of and close to the large spiral. To me the sound is quite as loud as when you heard it; but now you are one and all totally deaf to it. My original object in constructing two large spirals was to ascertain whether the inductive lines of force given out from one source would in any way inferfere with those proceeding from another source. By the aid of this simple iron disc and magnet it can be ascertained that they do in no way interfere with each other; therefore, the direction of the lines proceeding from each spiral can be distinctly traced. For when the two spirals are placed parallel to each other at a distance of 3ft. apart, and connected to independent batteries and transmitters, as shown in Plate 7, each transmitter having a sound perfectly distinct from that of the other, when the circuits are completed the separate sounds given out by the two transmitters can be distinctly heard at the same time by the aid of a telephone; but, by placing the telephone in a position neutral to one of the spirals, then only the sound proceeding from the other can be heard. These results occur in whatever position the spirals are placed relatively to each other, thus proving that there is no interference with or blending of the separate lines of force. The whole arrangement will be left in working order at the close of the meeting for any gentlemen present to verify my statements or to make what experiments they please.

In conclusion, I would ask, what can we as practical men gather from these experiments? A great deal has been written and said as to the best means to secure conductors carrying currents of very low tension, such as telephone circuits, from being influenced by induction from conductors in their immediate vicinity employed in carrying currents of comparatively very high tension, such as the ordinary telegraph wires. Covering the insulated wires with one or other of the various metals has not only been suggested but said to have been actually employed with marked success. Now, it will be found that a thin sheet of any known metal will in no appreciable way interrupt the inductive lines of force passing between two flat spirals; that being so, it is difficult to understand how inductive effects are influenced by a metal covering as described.

Telegraph engineers and electricians have done much towards accomplishing the successful working of our present railway system, but still there is much scope for improvements in the signalling arrangements. In foggy weather the system now adopted is comparatively useless, and resource has to be had at such times to the dangerous and somewhat clumsy method of signalling by means of detonating charges placed upon the rails. Now, it has occurred to me that volta induction might be employed with advantage in various ways for signalling purposes. For example, one or more wire spirals could be fixed between the rails at any convenient distance from the signalling station, so that when necessary intermittent currents could be sent through the spirals; and another spiral could be fixed beneath the engine or guard's van, and connected to one or more telephones placed near those in charge of the train. Then as the train passed over the fixed spiral the sound given out by the transmitter would be loudly reproduced by the telephone and indicate by its character the signal intended. One of my experiments in this direction will perhaps better illustrate my meaning. The large spiral was connected in circuit with twelve Leclanché cells and the two make and break transmitters before described. They were so connected that either transmitter could be switched into circuit when required, and this I considered the signalling station. This small spiral was so arranged that it passed in front of the large one at the distance of 8in. and at a speed of twenty-eight miles per hour. The terminals of the small spiral were connected to a telephone fixed in a distant room, the result being that the sound reproduced from either transmitter could be clearly heard and recognised every time the spirals passed each other. With a knowledge of this fact I think it will be readily understood how a cheap and efficient adjunct to the present system of railway signalling could be obtained by such means as I have ventured to bring to your notice this evening.

Thus have I given you some of the thoughts and experiments which have occupied my attention during my leisure. I have been long under the impression that there is a feeling in the minds of many that we are already in a position to give an answer to almost every question relating to electricity or magnetism. All I can say is, that the more I endeavour to advance in a knowledge of these subjects, the more am I convinced of the fallacy of such a position. There is much yet to be learnt, and if there be present either member, associate, or student to whom I have imparted the smallest instruction, I shall feel that I have not unprofitably occupied my time this evening.

## HAMMOND ELECTRIC LIGHT AND POWER SUPPLY COMPANY (LIMITED).

An extraordinary general meeting of this Company was held at the Cannon-street Hotel on the 10th inst., for the purpose of considering resolutions (which have already been published in *The Electrician*) for amalgamating with the Company the Yorkshire and the Birmingham and Warwickshire Brush Electric Light and Power Companies, and the undertaking known as Ferranti, Thompson, and Ince (Limited). Sir Chas. L. Young, Bart., presided.

The SECRETARY (Mr. Philip A. Latham) having read the notice convening the meeting,

The CHAIRMAN said: The notice just read is rather long, and it contains seven separate resolutions, which I am going to ask you to-day to pass if you approve of them. You will have observed that they all of them deal with the policy of amalgamation, or, as I should prefer to call it, of consolidation; and from the way this circular has been received by our shareholders, as far as we are able to judge, it appears to be a policy that commands their assent. You will understand that the existence of a great many competing companies has induced many of our would-be customers to withhold their orders on the plea that they never know exactly which is the best system, and they would wait really for some one to come and do the work for nothing. The result is that a great deal of installation work has been done practically for nothing, and the various companies, with their different systems, have been doing nothing more or less than cutting each other's throats. We cannot suppose next year, if there is another exhibition down at South Kensington, that they will get three of the electric light companies to go there and do the work required of them for nothing. There is no doubt that a great deal of the success of the Fisheries Exhibition has been due to the way in which it has been lighted up by the electric light companies. Our view is that there should be a proper and business-like understanding between electric light companies, and the first step, we think, in this direction, is to consolidate the existing business as far as we can, and thereby lessen all expenses. Circumstances have rendered it desirable that we should re-absorb two of the sub-companies we formed some time ago—namely, the Yorkshire and the Birmingham and Warwickshire Companies—and after a good deal of negotiation we have met each other on the terms embodied in the agreements which we are now placing before you. You see the electric light has not turned out exactly the very simple affair that so many thought it would during the rage for buying concessions, and the consequence has been that several companies have been, or are now in the process of being wound up. I think we had more faith in the substantial future of the business than outside persons who formed companies, and then because difficulties of one kind and another arose and the gold mine did not appear immediately in sight abandoned their interest and undertakings, not so much in despair as in impatience. We, however, have been working along steadily. We have had our disappointments, but we feel most decidedly encouraged to persevere by the success now attending our efforts, the prospects opened out to us by the constant inquiries which are made, the estimates we are requested to give, and the orders we have to fill. Therefore we were most anxious, as failure is almost always demoralising, that none of our sub-companies should come to grief, and so, after anxious consideration and great deliberation with the managers of these companies, we came to the conclusion that we had far better unite, take over the goodwills of their businesses as going concerns, and pay for them in shares of this Company, and then push forward the foundations which they had laid. We believe that with our large and competent staff and the practical experience we gain every day we shall be able to extend the business more satisfactorily in the large towns of Birmingham and Yorkshire, and with more advantage to ourselves, than if the original schemes were adhered to. It has become apparent to us that the sub-companies had not enough capital. With regard to the other company, the Ferranti Company is a manufacturing company, originally formed for the purpose of working the patents of which Sir William Thomson, Mr. Ferranti, and Mr. Ince were the inventors and owners. We have found the dynamo they manufacture admirably adapted to the purposes of incandescent lighting both in our efforts to solve the economical problem and to reduce the first cost of the electric light. We concluded that it would be better and cheaper for us to acquire the manufacturing and to have it entirely under our own control, so that we might be in a position to supply good work and to manufacture a great deal of the plant other than dynamos that we at present have to purchase from the manufacturers. No doubt you will be very glad to hear Mr. Hammond speak on this matter, and I shall move the first resolution and ask him to second it and speak about it. He concluded by moving the first resolution, expressing the expediency of effecting the amalgamation of the Yorkshire Company and the Hammond Company.

The MANAGING DIRECTOR (Mr. Robert Hammond) seconded the motion, and, in the course of his remarks, said: At the outset of his speech the chairman dealt with the question of the advisability of the amalgamation of the existing electric light companies. I suppose he would almost have said, if he had ventured to do so, of all the existing electric light companies, because we must feel that such an end as that would be extremely desirable. At the present time we have on the one hand the public anxious to have the electric light. I say these words quite advisedly. If we think for a moment, we can recall to our minds many instances where it has been quite decided that the electric light is far superior to any other illuminant. Take, for instance, the very good example of electric lighting at the Savoy Theatre. Every one spending an evening there comes away feeling all the more pleasant at the knowledge that he has not been breathing vitiated air. And if you go to a large hotel, like the Grand Hotel, you can eat your food with much greater comfort, in the knowledge that you are not at the same time consuming a certain proportion of very deleterious chemicals. If the point were put before the proprietor of every theatre in the country, it would be found that there would be an almost unanimous vote in favour of the electric light, if it could be supplied to him. The same remark applies to hotel lighting. In the case of any new hotel the application of the electric light is now taken into consideration, and the First Avenue Hotel, in Holborn, to be opened in about a fortnight, will have the electric light applied to it to the extent of 1,200 lights, and this is to be by the Hammond Company. If you go on to the question of the lighting of factories, it is becoming evident throughout the country that the great advantages of the electric light are being more and more recognised. Its safety is strongly felt, particularly, say, in the lace manufactories of Nottingham, and other branches of industry where inflammable materials are present, and the health of the workpeople makes an effect on the quality of the goods. If we refer to collieries and railway carriages we see other large fields for the electric light, where its advantages are admitted. I hope, therefore, you will be unanimous in thinking that I have made good my proposition that the public are anxious to have the electric light. On the other hand you have a large number of companies with one object and one view—the solitary, one ulterior object of supplying the electric light. There are not, after all, though, many of these companies. One talks of a large number of them, but looking at it from a broad point of view the number is really comparatively small, and the amount of capital invested in them is so insignificant

Digitized by Google

that one can hardly regard it as forming a factor in the future of this industry. Unfortunately existing companies, though all desiring to supply the light, wish to do so in a different way. The public therefore say to the companies, we will wait till you have made up your minds how we are to have the electric light, and one feels that they have justice on their side. Speaking for the directors of this Company, I am able to say that their aim has been and will be to overcome this anomaly and strive for one united electric light company to really deal in a comprehensive manner with the immense amount of electric lighting which has to be done, and to be done in a very short time. With this object in view the resolutions will be put to you this morning. I may say that, feeling that every effort should be made for effecting this object, we have made a settlement with the Brush Corporation. That dispute, which has now been open for a matter of a year, is now practically settled, for though the agreement itself has not actually been signed, the heads of it have been approved. I am able to say with the concurrence of the vice-chairman of the Brush Corporation, Mr. Sellon, that the arrangement is one honourable and equitable as regards both parties. After what I have said as to the advisability of amalgamation you will quite imagine we felt, as to the two companies which are off-shoots of our own, that if we were earnest in our belief that there should be one electric light company, these two concerns should be no longer carried on under separate management. As to the Birmingham Company, I do not wish to say one word against the directors of that company, as they have worked as hard as they could to make that company a success; but, unfortunately, there was no knowledge of electricity on the Board. They always had to apply to the Hammond Company whenever they wanted any electrical advice, and when I was in America they asked me to join their Board, which I gladly did. Shortly after I joined them I went into the question of its union with the Hammond Company, and the results of the efforts which have been made on the one hand by myself and on the other by Mr. Felton—the late chairman of the Birmingham Company, for the news of his sudden death surprised us last week—the result of our exertions has been the amalgamation of the two companies. I have this morning been occupying the rather invidious position of presiding over a meeting of the Birmingham Company, and it was not an easy task, for the meeting lasted an hour, and I had to battle with a good many objections that were raised there. In the end, though there were some dissentient votes, the matter was carried, and the Birmingham Company are pledged to carry out this amalgamation if you also think well of it. If you do not the whole amalgamation falls to the ground. Though we take over the business of the Birmingham Company, and are paying them no cash, but issuing to them a certain number of shares in the Hammond Company, we are getting in return very solid assets. They have £9,000 deposited at the bank among other assets, and this will strengthen the backbone of the Hammond Company in the event of our attaining what we are striving for—the amalgamation of all the electric light companies. When the time comes for such a proposition as that to be considered those who have the largest cash balances will be able to take up a pretty strong position. The value has been agreed also at a meeting of the Yorkshire Company, and we were obliged to meet to-day—unfortunate though it is—or the whole of the arrangements would have been jeopardised. The 10th of November was the last day, but when that date was fixed on it was felt that there would be ample time to get the agreements ready and to settle all the schedules; but you know how things go when they have to be put in legal shape. The same remarks which I have made about the Birmingham apply almost to the Yorkshire Company. In my visits to Middlesbrough I have been very pleased to see the solid foundation established there for supplying customers. The opponents of this Company do not choose to understand the large extent of the operations of the Hammond Company. As to the Ferranti Company, that is taking a step which in the opinion of the Board is a momentous one, and one upon which the future of this Company will very largely hinge. You remember the last time we met it was stated that the Hammond Company were agents for the Ferranti machine, and they felt it desirable then to keep up the agency, leaving the manufacturing company to do the making of all the plant. It very soon came to be evident that the division between the agent on the one hand, who wanted a certain machine, and the manufacturer on the other, who thought he should sell a particular machine, was not going to be very pleasing to the Hammond Company, and it also became evident that the electric lighting company that was going to live and do work in the future must have works at command to supply the articles necessary in carrying it on. When a man is going to adopt the electric light, he says you must do the whole work for a certain fixed sum. We find ourselves, however, giving orders for certain things, very small in themselves, but upon which we pay a profit to the maker of 40 or 50 per cent. I do not say that we are going into the manufacture of electroliers, which are manufactured so well by Verity Brothers, but when it comes to a question of making fuses, switches, and several other things, we think it is better that they should be manufactured by the Hammond Company. That view has guided the directors very strongly in their amalgamation with the Ferranti Company. They found the position of the Ferranti Company thus:—About a year ago some £36,000 cash was subscribed and put into that company, and it has been very well used in that company since. There are, of course, those who deride the Ferranti machine. The bulk of this money went in the formation of works, which have been highly complimented by our friend, Sir William Thomson, to whom we are paying a royalty on the machine. I am glad to say that, as it ensures his advice at any critical moment when we require it, and at the works his handiwork is visible in every corner. We are not bound for all time to make this particular machine, but it is the best at present for large installations. Whatever may come in the future, however, we have by this amalgamation works and tools ready for application for any of the purposes of the Company. Against that £36,000 paid in cash we are going to give £36,000 in ordinary shares of the Hammond Company. I do feel that a more honest bargain was never made than this particular one. That covers the question of the works. Then we had to deal with certain gentlemen who did not form part of those who subscribed the £36,000, but who really held the patents. They held B shares on which they were to receive deferred interest, those who subscribed the £36,000 having A shares. To those who held the patents we said we would, on their handing over the patent of the Ferranti machine, and those of Sir Wm. Thomson and Mr. Ince, give £80,000 in shares of the Hammond Company, on which no dividend is to be paid until 5 per cent. is paid on the whole of the rest of the Hammond Company's capital, including that representing the £36,000. It has been said by some, as to this, that the Hammond directors are going along rather fast, and are "watering the stock." That, however, cannot truly be said, because though we do issue more shares such material and solid assets are obtained in exchange that we shall be able to earn with those assets a much larger dividend than that absolutely represented by the new shares. It has been said that not much is heard about the Ferranti machine. A gentleman closely connected with the Brush Company said something to that effect to me yesterday. I have told you that our dispute with the Brush Company is at an end; and with regard to the Brush arc machine, against which I have never said a word, it will be used by us for all arc light purposes. We do, however, say that that company is deficient in regard to an incandescent machine. We feel that the incandescent machine of the future must cope with the incandescent work that must come in the future, not the lighting up of a shop, but the lighting of an immense district—house to house lighting, in fact. How many times we are told, "If you would only apply the thing to my house as gas is applied, I would willingly pay two or three times the price paid for gas." For the large amount of incandescent lighting that is immediately coming upon us we want a machine that will run at least 1,000 lights. We hope, in a short time, to be able to tell you that we have 10,000 running from one centre, and we have that in the Ferranti machine. It was said to me yesterday by a gentleman that he did not know of a single successful installation of the Ferranti machine throughout the country. In the City, however, it is not our course to tell everything that we are doing—our work there is directed to obtaining business. I went home last night saddened to think that there should be even one gentleman who thought that we were proposing to take over something, as regards the Ferranti amalgamation, that was not worth anything. On arriving home I found my house brilliantly illuminated by the working of the Ferranti machine, and I have had nothing but that machine in use for the last year, and it has worked without fault. My gardener, too, is my chief electrician. I therefore contend that the Ferranti machine does its work well. People say you want an advanced scientist to look after these machines, but in my case it is, as I have said, my gardener who looks after it. I would have no hesitation in taking home our greatest opponent and showing him what can be done with the Ferranti machine. I am accustomed every fortnight or three weeks to have an electric light night at my house. The 12th is my next of these nights, and I shall be happy to see any gentleman present on that occasion, and if he cannot come that night the next night will be December 1. I think the payment of £36,000 in ordinary shares of the Hammond Company against the £36,000 cash that was subscribed in the Ferranti Company must commend itself to you. Of course it would be a bad bargain if the money put into the Ferranti Company were lost, but one is able to point to the works near Broad-street Station as the result of the money put into the Ferranti Company. I feel as a shareholder in both companies that the bargain is most equitable. If that is so we do not grudge £80,000 to the holders of the patents. The Ferranti machine has shown itself capable of coping with the problem immediately before us of house-to-house lighting. It is doubtful whether that will be done with a high tension machine and accumulator; and I may say that very active minds are being directed to the subject of an accumulator. In a fortnight you will be able to see the installation at the First Avenue Hotel, and I believe it will be the largest installation in the world. I see all over England, I am very glad to say, an inclination on the part of our large towns to take up this matter on a thorough and broad basis. We have been constantly asked during the last year "How is it that the electric light companies do not make more show?" Those who ask this question seem quite to overlook the fact that there are millions upon millions, one may say, invested in gas, and it is expected of the electric light companies, who are so few comparatively in numbers, and whose means are so limited, that they are to cope in capital with the immense resources invested in gas. When the public have determined that the electric light can be supplied on an economical and a reliable basis, then they will be willing at their various towns to agree to their town councils raising the necessary funds and taking the electric light into their own hands, and we shall have dotted about in every part of the country customers willing to come to us to carry out the engineering works. Though the capital for electric lighting will require millions, a company with £50,000 at its back will be able to do the engineering work throughout the country. At Brighton they have decided not to wait for the day when an electric lighting company will put up the apparatus on hire, but to do the thing themselves. I was at the Brighton Town Council last Tuesday, and a resolution was passed that £60,000 should be spent there on the electric light. The directors of this Company feel very greatly interested in this, and I hope that the first piece of lighting at Brighton—that of lighting the "front"—will be put in the hands of this Company, and I have grounds for hoping that. The towns gradually are making up their minds to have the electric light, and, if so, it must be supplied as gas is, from a large centre. The nearer we get to the problem the nearer we shall get to the application of electric lighting all over the kingdom; and those who, like ourselves, have works will be able to cope with the business that comes in. I am confident in saying that the only company that is well advanced with a machine to cope with that business is the Hammond Company if the resolution as to the Ferranti Company is passed by you to-day.

A SHAREHOLDER asked the liabilities which were being taken over with the companies to be amalgamated.

MR. HAMMOND, in reply, stated that the exact assets of the Birmingham Company, taken out by the accountant of the Hammond Company, were £9,171; an installation payable over seven years, £2,364; and the total assets of the Birmingham Company were £12,000 odd. Included in the total of the liabilities of that company (£2,300) is £1,000 due to us. The Yorkshire Company's amalgamation was put down as having assets of at least £14,000. Our accountants have gone very carefully into the figures, and we make the assets £15,600, and there is an amount of £5,400 on machinery. The total of all the installations in the Yorkshire Company is £7,800, the principal of which is in Middlesbrough, and may be turned at any moment into cash. The total of their assets is £17,000, sundry liabilities are £1,398, the net balance being £15,600. We give them in return £22,435 in shares of the Hammond Company. It is a decided advantage for us to have back Yorkshire, especially as the Leeds

Digitized by Google

Council have made up their minds to have the electric light. As to the Ferranti Company, the liabilities are practically *nil*. We owe them the money that is coming for a machine for the First Avenue Hotel, and they have practically paid all theirs. The net amount that is to come to us is identically that which first went into the concern. Of the £36,000 cash £10,000 was paid partly to Sir Wm. Thomson and partly to those who conducted the earlier experiments. The building does not belong to the Ferranti Company. The Ferranti assets include a machine at first cost that is capable of running 3,000 lights.

Mr. HARLEY inquired what sum had been set apart to meet the claims of Mr. Liardet and another gentleman against the Company.

The CHAIRMAN said he did not think this question had anything to do with the object of the meeting. He might, however, state that they did not admit any liability in connection with the claim of Mr. Liardet, and no sum had been set apart for the purpose.

Mr. HAMMOND: Mr. Liardet owes us money.

The CHAIRMAN (to Mr. Harley): I see you have only one share in this Company, and we can pretty well guess how you got it [laughter]. He then put the resolution, which was carried with one dissentient, Mr. Harley.

On the motion of the CHAIRMAN, seconded by Mr. HAMMOND, the resolutions approving the amalgamation with the Birmingham and the Ferranti Companies were also passed with one dissentient, as before.

The CHAIRMAN afterwards referred with satisfaction to the settlement of the dispute with the Brush Corporation, and stated that the only action in which the Company was concerned was the one which had been referred to by Mr. Harley, in connection with which they admitted no liability.

The proceedings then terminated.

## BIRMINGHAM AND WARWICKSHIRE BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

A special general meeting of this Company was held on the 10th inst., at the Cannon-street Hotel. Mr. Robt. Hammond occupied the chair.

The CHAIRMAN, before proceeding with the formal business, expressed the great sorrow he felt at the sudden death of the late chairman of the Company. The project which was about to be placed before the shareholders was one that wholly emanated with the late chairman, and therefore he should ask them to believe that in taking the chair that day he should endeavour to represent to them the feelings which would have been represented, and put before them the views which would have been enunciated, by their late chairman. He would now call upon the secretary to read the formal notice of the meeting.

The SECRETARY having read the notice,

The CHAIRMAN said legally the resolutions must be put separately, but what he had to say would be on the first one. The agreement which was to be submitted to them had not received the assent of the Hammond shareholders, and therefore their directors must ask for a certain amount of trust to be placed in them. Without going too closely into the question of accounts he could assure them that their late chairman took care that the arrangement under the proposed amalgamation with the Hammond Company should be more beneficial to this Company than an arrangement arising from the distribution of the assets of the Company among the shareholders. The Hammond Company felt themselves justified in giving the terms agreed upon, because they had an equipped staff and a perfect knowledge of the business of the district, and were ready to take it up at once. The Hammond Company felt it to be to their benefit to work the district. With respect to the question of amalgamation of the electric lighting companies, there were not many companies at present in the field, but the number was sufficient to puzzle the public as to which had the best system. Those who had to conduct the electric lighting of England felt that the public mind should be clear on that point, and that the various companies should unite if possible. When electricians were divided into separate camps the public were discouraged, and asked how long this was to last. The step now proposed to be taken was the first step with the object of showing that the leading electric companies felt an undivided front was better than scattered interests. His observations had reference to those whose business was almost wholly—like that of this Company—to supply plant, and with the view to show that the expenses of the management of this Company would be by the amalgamation saved to the shareholders. The cost of separate offices and establishments would be done away with. He would now call upon Mr. Brown, of Messrs. Linklaters, to explain the nature of the agreement.

Mr. BROWN stated that the agreement recited that there were 39,341 shares of £2 each of the Birmingham and Warwickshire Company outstanding, all of which were fully paid-up with the exception of the £60 mentioned in the balance-sheet; 7,947 shares were now the property of the Hammond Company. The agreement provided that the Hammond Company should on the 30th November allot and issue to that Copmany one fully paid-up share of the Hammond Company of £5 for every six fully paid-up shares of £2 in the Birmingham Company, and the shareholders of the Birmingham Company were to accept those shares in discharge of every claim. The Hammond Company were to surrender to the Birmingham Company the 7,947 shares they held in that Company, which were to be cancelled. By Clause 5 the Hammond Company were to pay all debts of the Birmingham Company. The Hammond Company agreed to pay all the costs of the amalgamation, and the winding up of the Birmingham Company. In case the agreement was not confirmed at the meeting of the Hammond Company, either company might rescind it.

A SHAREHOLDER remarked that he understood the shares to be allotted were not likely to be quoted on the Stock Exchange.

The CHAIRMAN replied that application would be made to the Stock Exchange for a quotation in due course. He then moved, "That it is expedient to effect an amalgamation of the Birmingham Company with the Hammond Electric Light and Power Supply Company (Limited).

The resolution was seconded by Mr. C. R. HOARE.

Mr. THOMAS BEARD wished to know whether the directors had hitherto taken fees?

The CHAIRMAN said the share capital of the Hammond Company was £250,000, which they had power to issue from time to time. Of that amount £125,000 was issued at the incorporation of the Hammond Company, leaving £125,000 still to be dealt with. The £125,000 at present quoted on the Stock Exchange was in the hands of various individuals, but the Hammond Company had no power to buy up its own shares; therefore the shares to be issued to this Company, though not newly created capital, were not yet quoted on the Stock Exchange. Application would be made for a quotation, but it was impossible to say what the result of the application would be. It should be borne in mind that the shares would be negotiable even if not quoted. There were buyers and sellers for everything under the sun. With respect to the directors' fees, he had been but a short time on the Board. At the general meeting held this year it was stated by Mr. Felton that the directors, in the absence of a profit, had waived their right under the Articles of Association to have £1,000 divided amongst them, and had only taken £700. They had had a very anxious year, and it was not the fault of the directors that no profit had been made. He might say that he, as representing the Hammond Company on this Board, should take nothing. This Company had £10,000 of assets, for which they were to get about £17,000 in shares of the Hammond Company. They would save the expenses of management, and the Hammond Company would not require to increase its staff to do the work, and probably they would be able to make a profit when this Company had made a loss.

Mr. BEARD observed that he had not heard any account given of the assets of the Hammond Company. He thought it better to have this Company wound up, and take what they could get of the £10,000, even if it did not amount to 5s. in the pound.

The CHAIRMAN remarked that the holders of 22,000 out of 27,000 shares had assented to the scheme as proposed. If this Company were wound up the costs of liquidation would absorb a portion of the £10,000 assets, and the Hammond Company, as holders of nearly 8,000 shares, would claim to participate in the distribution of the assets. On the other hand the proposed arrangement would give the shareholders in this Company £17,000 worth of shares in the Hammond Company, who would at the same time give up their claim to their 8,000 shares.

The resolution was then put and carried.

The following resolution was then agreed to:—"That the draft agreement now submitted to this meeting, and expressed to be made between the Birmingham Company of the one part, and the Hammond Company of the other part, be, and the same is hereby approved, and that the Board of the Birmingham Company be, and they are hereby, authorised to enter into and carry the same into effect."

A vote of thanks to the chairman terminated the proceedings.

## NOTES.

ARC LIGHTING IN THEATRES.—Arc lights are to be tried in the Opera House at Hartford, Connecticut, U.S.A.

NEWINGTON.—The Newington Vestry have decided not to proceed with the necessary steps for procuring a provisional order to supply electricity in their district.

SALE OF ELECTRICAL PLANT.—We notice that the plant belonging to the Duplex Electric Light Company is to be sold shortly by Messrs. Frank Lewis and Co., under an order of the High Court of Justice.

PATENTS AND POST OFFICE SERVANTS.—The Postmaster-General has issued an order prohibiting officers of the department taking out any patent for an invention without his consent being previously obtained.

HEAD LIGHTS FOR LOCOMOTIVES.—American papers say that the Smith-Woolley electric head light for locomotives has been tried at Indianapolis with satisfactory results, the jolting of the engine having no effect on the steadiness of the light.

THE LATE CROMWELL VARLEY.—At their meeting on the 2nd inst. the New York Electrical Society passed a series of resolutions expressing their sincere regret at the death of the late Mr. Varley, and the loss sustained by electrical science thereby.

CABLES REPAIRED.—The Indo-European Telegraph Company notify that, the cables of the Indian Government in the Persian Gulf being now restored, the company is prepared to accept messages for transmission between this country and India, China, &c.

LIGHTING CARRIAGES.—The *Morning Post* says that the Milan omnibus and brougham companies have made experiments in lighting their vehicles by electricity. These, it is said, were most successful, and it is considered likely that the system will be adopted.

TORPEDO CABLE.—The Admiralty, with the view of undertaking extensive torpedo experiments, have ordered of Messrs. Siemens 20,000 yards of countermining cable, of which 13,000 yards are to be supplied to Portsmouth Dockyard, 5,000 to Devonport, and 2,000 to Chatham.

ACTION OF METALS IN ELECTROLYTES.—On Thursday last a paper was to be read at the Royal Society by Dr. G. Gore, on "Some Relations of Heat to Voltaic and Thermo-Electric Action of Metals in Electrolytes," to be illustrated by a new form of thermo-electric pile for measuring small electric potentials.

THE ADELAIDE GALLERY.—In our note on the fitting up of the Edison system in Messrs. Gatti's Adelaide Gallery, in the Strand, in last week's issue, we omitted to state that the brass fittings have been made for Messrs. Gatti, to special designs, by Messrs. Verity and Sons, of King-street, Covent Garden, W C.

LONDON PLATINO BRAZILIAN TELEGRAPH COMPANY.—The directors of this company have declared an interim dividend of 2s. per share in respect of the six months ending June last. The revenue of the company for the month of August, 1883, is estimated at £1,548 (Western Brazilian portion £946, land lines £602).

THE JABLOCHKOFF COMPANY.—Mr. Pennington, a shareholder in the above company, has withdrawn his petition for a compulsory winding-up order. It appears that this is the result of a cross-examination of the secretary and general manager of the company by a special examiner appointed by the Court, and a detailed examination of the company's books and papers.

IRON WORKS LIGHTING.—The Hammond Electric Light Company last week lighted up for the first time the Derwent Iron and Steel Works, Workington (Messrs. Cammell and Co.). The plant consists of a 16-light Brush machine, from which are run eighteen lamps. The installation was erected by the Manchester branch of the Hammond Electric Light Company, under the superintendence of Mr. F. D'A. Goold.

THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.—A considerable body of the members and council of this society assembled at their usual place of meeting on Thursday evening last in order to mark their respect for their past President, Sir William Siemens, by postponing the reading of the papers fixed for that meeting, and passing a vote of condolence to the members of his family. Next Thursday evening is fixed for the reading of the postponed papers.

WIGAN COAL AND IRON COMPANY.—We mentioned some few weeks back that this company were about to light their new pit with incandescent lamps. This has now been done, and the installation has been running for the last two weeks. The plant consists of a Victoria incandescent machine and Swan lamps of 50 candle-power nominal each, a set of which are about 150 yards down the pit, where they are attached to a circular tube, which can be raised and lowered to meet the requirements of the work, the cable being wound upon a drum in the engine house. This installation has been erected by the Manchester branch of the Hammond Electric Light Company, under the superintendence of Mr. F. D'A. Goold.

THE WESTERN UNION TELEGRAPH COMPANY.—From the London office of this company a pamphlet copy of the president's annual report to the meeting of stockholders in New York on 10th ult. has just reached us. We have had time only to glance at the contents, and may have something more to say about them on a future occasion. For the present, however, we may opine that the company have some object to serve in distributing a full account of their affairs for the information of people in this country. What that object is will not be hard to conjecture; whether it will be attained depends very much upon the English public taking on trust statements and figures the local and true significance of which it is impossible for them to form a correct opinion.

OVERHEAD WIRES IN THE COUNTRY.—Whilst the London local authorities are making up their minds to ascertain, and that quickly, what authority they have over overhead wires in London, the question has been summarily decided in the country. At the Peterborough County Court on Thursday week Thomas Johnson, surveyor of highways in the parish of Walton, Northamptonshire, objected to the Post Office stretching overhead wires in his parish. The county court judge held there was no ground for his objection. He did not think overhead wires were dangerous, and to object to their presence in a small village was unreasonable. Mr. Casserley, on behalf of the Postmaster-General, said the case was a test one, which would rule many other similar objections.

SIGNAL SERVICE CLOCK.—A clock of peculiar construction has been manufactured for the United States Signal Service Bureau at Washington. The case is of brass, and allows the swing of a pendulum 39in. long; it is air tight, and admits of the air being exhausted, and the movement

Digitized by Google

run in a vacuum, thus obviating any possibility of variation due to atmospheric changes. An electrical attachment is connected with the movements, by means of which the clock is wound as it runs, so that there is not the usual liability to variation arising from the differing conditions of the main-spring. This is accomplished by alternately breaking and closing an electric current. The motion thus obtained and the power of the current are used to rewind the spring by means of a worm and other mechanism. The winding keeps exact pace with the running, and the slightest deviation from this standard is shown on an indicator. The train is jewelled, and is therefore little affected by friction.—*Scientific American.*

Brighton and the Electric Light.—At the meeting of the Brighton Corporation on Wednesday, Mr. Carpenter was to move a resolution deferring until September next the consideration of measures to be adopted in carrying out the powers obtained from Parliament by the Brighton Electric Order of August last, under which it is necessary that the requisite apparatus for lighting a specified portion of the borough should be completed by August, 1885. In accordance with the recommendation of a committee appointed to deal with the subject, the corporation, after obtaining the sanction of Parliament, resolved to secure a certain site for works, and to apply to the Board of Trade for authority to raise a loan of £60,000, although only half that sum would be required during the ensuing two years, and the repayment of the loan was to be extended over half a century, the corporation in the meantime receiving rents from customers. Mr. Hall was to ask the council practically to rescind these resolutions.

Telegraph Materials Wanted.—The Cheshire Lines Committee are inviting tenders for the supply of telegraph wire and materials for the year 1884. Patterns can be seen and specifications, with forms of tender, obtained upon application to Mr. W. H. Legge, storekeeper, Cheshire Lines, Warrington. Sealed tenders, endorsed "Tender for ——," must be in the hands of Mr. Edward Ross, secretary, London-road Station, Manchester, addressed Cheshire Lines Store Department, Warrington, by 12 noon on the 3rd December. The Directors of the North Eastern Railway also invite tenders for the supply during the six months ending 30th June, 1884, delivered carriage paid at the company's telegraph stores at York, of—1, telegraph apparatus; 2, telegraph wire and line stores. Forms of tender may be had on application to Mr. Graves, Telegraph Department, York; and tenders must be sent in to the secretary at York, sealed, and marked "Tender for Telegraph Stores," by noon on the 28th inst.

What Followed from a Small Mistake.—Every one has heard of the shoemaker's ambitious sign, "Mens conscia recti," and of the rival tradesman who paraded "Mens and womens conscia recti" on the other side of the way. An incident which recalls this time-honoured Joe Miller occurred in connection with the recent banquet of the Métropolitaine Electrique in Paris. The motto of the company is "E fulmine lux et robur," but by a perverse ingenuity on the printer's part it was presented in such typographical guise on the invitation cards that some of the guests—men, doubtless, who had sacrificed the humanities to science—got the notion that the invitations came from a firm composed of M. E. Fulmine and two partners. Several acceptances were addressed to this imaginary trio, and one individual even went to pay his respects to M. Fulmine in person. A waggish clerk, who appreciated the situation in a moment, told him that all three partners were out at the time, but that he would not fail to present his compliments to them when they came back.—*St. James's Gazette.*

Large Cable Contracts for Birmingham.—The local copper wire trade is just now in a state of considerable buoyancy, says the *Birmingham Daily Post*, consequent upon the receipt of some important contracts for cable wire. A few weeks since a large contract for a new Brazilian cable was secured by Messrs. John Wilkes and Sons and Thomas Bolton and Sons, and within the last few days another contract, this time for 400 tons of copper wire for a new Atlantic cable, has been divided between the firms named and Elliot's Metal Company. As the wire is urgently wanted, it is being turned out at the rate of about ten tons a day. In both cases the contracts have been taken at exceedingly low prices, although the wire, as usual, has to be of the highest quality, tensional strength, and conductivity. Negotiations are proceeding for one or two other contracts of a similar character, which have been a good deal discussed of late, but one at least of these projects is pretty sure to be abandoned. The iron wire for cable covering purposes will probably be obtained principally from Warrington, but it is understood that about 1,000 tons of galvanised wire will be supplied by Shropshire firms.

The Attack on Electric Light Engineers.—Some days ago four young men attached to the Swan Factory in Paris, whilst attempting to rescue a workman from ill-treatment at the hands of some other men, were themselves attacked and badly hurt, knives being used against them. The following information given by the *Standard's* Paris correspondent will therefore be read with interest. Telegraphing on Sunday night, he says:—"On calling yesterday at the Swan Electric Light Factory to inquire after the four English youths whose heroic rescue a few days ago of a workman from outrage provoked an attack upon themselves, I was fortunate enough to meet the manager, M. Cherrill. I learned that two of the men were out of doors again, but the other two were still in the hands of the doctor. It is right to state that M. Cherrill does not concur in the slight estimate of the affair expressed to me by the secretary of the Paris Municipal Police. On the contrary, his opinion is that had his men not been steady and of robust constitution, serious consequences might well have ensued, at least in one case. A second man has been arrested in connection with the affair. He, too, is an Alsatian."

On a New Theorem in Dynamic Electricity—In a recent number of the *Comptes Rendus* M. L. Thévenin has an article on this subject, of which the following is an abstract: "Given a known system of connected linear conductors, including known electromotive forces $E_1 E_2, \ldots E_n$, two points are taken as A and A′ possessing potentials V and V′. If the points A and A′ are connected by a wire A B A′ of resistance $r$, containing no electromotive force, the potentials of the points A and A′ take values differing from V and V′, but the current $i$ which circulates in the wire is given by the formula $i = \frac{V - V'}{r + R}$, in which R represents the resistance of the primary system, measured between the points A and A′ considered as electrodes. Ohm's formula is thus applicable not only to simple electro-motor circuits, presenting well-defined poles, but to a net-work of conductors that may be considered as an electro-motor with arbitrary poles, of which the electromotive force is, in each case, equal to the difference of potentials pre-existing at the two points chosen as poles. This theorem, which has not hitherto been pointed out, is very serviceable in certain theoretical calculations, and in practice it admits of immediately evaluating, by means of

Digitized by Google

two data easily obtained experimentally, the quantity of current traversing a branch circuit that may be connected on to a net-work of conductors, without intimate acquaintance with the constitution of the net-work. The author demonstrates the theorem."—*Abstracts of Papers in Foreign Transactions*, published by the Institute of Civil Engineers.

The New Standard Wire-Gauge.—On Thursday week, the 15th inst., a deputation from the iron manufacturers of Staffordshire, Lancashire, Bristol, South Wales, and Scotland had an interview with Mr. Chamberlain, at the Board of Trade, with reference to the new standard wire-gauge which is to take effect in March next. Mr. Benjamin Hingley, chairman of the South Staffordshire Ironmasters' Association, said the circular sent out by the Board of Trade had taken them by surprise, and the standard had been adopted without giving the iron trade sufficient time to exercise any influence upon it, although it had been pointed out that the whole standard was inapplicable to the wants of the iron trade. Their objections were—first, that it would entirely disarrange a very complicated scale of wages based on the old Birmingham gauge, both as regards sheets and hoops; and it would be difficult to get foreigners to understand or sanction the new arrangement. The whole iron trade was now working upon the same standard, which was as nearly as possible that published by the South Staffordshire Ironmasters' Association, and this they asked should be made the legal standard gauge. Several other gentlemen having spoken, Mr. Chamberlain replied that the circular had been sent by the Department to the whole trade; and after receiving suggestions and criticisms, they submitted a second set of proposals, which were at once adopted by about 90 per cent. of the trade, and which had subsequently been created into an Imperial standard by an order in Council. This standard measure had been made Imperial for the first time; but there was nothing to prevent any one selling with any other gauge which he might select, provided that he notified the fact.—Mr. Hingley said they would take that into consideration.—Mr. Barker (Wolverhampton) said that for the heavier descriptions of iron they wanted a 112lb. weight instead of 56lb.—Mr. Chamberlain said that local authorities who were obliged to have these new standards objected to the cost.—The deputation then withdrew.

Overhead Wires.—The agitation against overhead wires is assuming form and acquiring substance. The local authorities of London are acting in unison in the matter instead of passing resolutions and appointing committees here, there, and everywhere, which may serve to show the necessity for action, but will not enable action to be taken. The Marylebone Vestry appear to be the centre of the movement, they having invited the other local authorities to send representatives to attend a general meeting for the consideration of the subject and their position in the matter. This meeting was held on Thursday week, the 15th instant, at the Court House, Marylebone, and was well attended. It was presided over by Mr. Charles Walker, churchwarden of the parish. Two reports were presented, one on behalf of the conference by the committees of St. Marylebone and St. James, Westminster, and another by the Vestry of St. George, Hanover-square. They both detailed what occurred upon the occasion of a deputation to the Local Government Board, when Sir Charles Dilke declared that the Government were of opinion that ample powers already exist by which local authorities can enforce control over all wires placed under or over the streets and thoroughfares of the metropolis. The united committee adopted a resolution that it was desirable that one local representative body acting for the whole of London should forthwith test the powers of the law on the question.—Mr. T. R. Endean, who had acted as chairman of the conference, moved "That this Vestry approves the principle of control by local authorities, and resolves that steps should be taken by this vestry to test the question as to the existence of such right of control; but that the mode of procedure shall be determined at a subsequent meeting."—Mr. Galsworthy seconded the motion.—Mr. Bulnois was perfectly in accord with the mover of the resolution and the committee as to the necessity of this point being settled for the benefit of the public; but he hardly thought it was sufficiently practical, and that it would tend to unnecessary delay. He therefore moved as an amendment to the latter part of the motion, that the subject should be at once referred to the parliamentary committee, with power to take counsel's opinion as to the proper course to be pursued, and report thereon to the vestry.—Mr. Reed seconded the amendment, which Mr. Endean said he would accept as a rider to the original motion.—The motion and amendment were then amalgamated into one resolution, which was adopted. Several letters detailing accidents that had occurred through falling wires were referred to the committee to report on.

Thermo and Actino-electricity of Quartz.—Herr W. Hankel contributes a paper to the *Ann. Phys. Chem.* on this subject, of which the following abstract appears in the *Journal of the Chemical Society* for this month:—The author, after enumerating the various results obtained in the course of his investigations on the phenomenon of pyro-, actino-, and piezo-electricity of quartz crystals, proceeds to discuss the points of difference between his results and those of Friedel and Curie. The latter have observed that pressure or cooling—approach of the molecules—and release of pressure or warming—separation of the molecules—call forth the same kind of electricity at the ends of the crystallographic axes. The results of the author are, however, in direct opposition to this simple rule, and the discrepancy is attributed by Friedel and Curie to an irregular cooling of the crystal. Secondly, the latter do not consider actino-electricity to be a particular phenomenon, but merely to be caused by an irregular heating of the crystal. In the present paper the author describes various forms of experiments made both to confirm his previous results, and to prove that the position of the poles is reversed according as the crystal is left or right handed. He has also extended his experiments on actino-electricity, which is shown to differ from pyro-electricity in that, firstly, the former causes a polarity of crystallographic axes precisely the reverse of that which would be produced by the latter were the ray of light merely a source of heat. Secondly, actino-electricity reaches its maximum about 40″ after the commencement of the radiation, and disappears at about the same interval of time after the withdrawal of the radiating body; whilst the pyro-electric difference of potential is slowly evolved by heating or cooling the crystal. Thirdly, it is proved that the actino-electricity is not produced by unequal heating of the crystal. But if the radiation be long continued, then from the warming of the mass of the crystal pyro-electricity is produced, causing ultimately an opposite polarity in the axes. Experiments are also quoted to show that actino-electricity is a reversible phenonmenon, for the approach of a cold body near a crystal causes an opposite polarity to that produced by a warm body. If Y be the maximum potential produced by a radiation of given intensity, and $y$ the time in seconds from the commencement of the radiation, then $Ay/dt = a(Y - y)$, where $a$ is a constant. By integration, when $t = 0$, $y = 0$

Digitized by Google

the formula becomes $y = Y - Ye^{-at}$; on removal of the source of radiation, when $t = 0$, $y = Y$, then $y = Ye^{-at}$. Experiments are quoted to prove the accordance of the values calculated from these formulæ with those obtained directly by experiment. The author has been unable to detect the phenomenon of actino-electricity in other hemimorphus and symmetrical crystals, with the one exception of cinnabar, which, like quartz, is hemimorphous in its secondary axes, and in the direction of its principal axes rotates the plane of polarisation. In conclusion, the author gives a list of substances, crystallising in perfectly symmetrical forms, which display the phenomenon of pyro-electricity. Regular System. *Fluorspar.* Tetragonal System. *Idocrase, Apophyllite,* and *Mellite.* Hexagonal System. *Calcspar, Beryl, Brucite, Apatite, Pyromorphite, Mimetesite, Phenacite, Pennine,* and *Dioptase.* Rhombic System. *Topaz, Heavy Spar, Celestine, Aragonite, Strontianite, Cerussite, Phrenite,* and *Natrolite.* Monoclinic System. *Gypsum, Diopside, Orthoclase, Scolecite, Datolite, Euclase,* and *Titanite.* Triclinic System. *Albite, Pericline,* and *Axinite.* The author has been unable to detect the phenomenon of piezo-electricity in perfectly symmetrical crystals.

Underground Lines in France.—On Thursday week M. Cochery, the French Minister of Posts and Telegraphs, made a series of experiments to test the working of the subterranean cables that have been laid in France. If the necessary votes of credit can be obtained it is intended that within the next four years subterranean cables of the length of seven thousand two hundred and ninety-six kilometres shall be laid. M. Cochery stated to those present that the subterranean lines already established gave most excellent results. He alluded to the vast subterranean system that has long existed throughout the whole extent of the German Empire. The German system, consisting of eight thousand kilometres of lines and a length of wire of about fifty thousand kilometres, was, M. Cochery said, the most complete in Europe. It was provided at the instance of Marshal Moltke, and its value in time of war could not be over estimated. *L'Electricien* says that experiment has proved that the French cables can be worked at the same speed up to 400 kilometres as overhead lines. By placing light relays at every 400 kilometres distance has practically no effect. Our contemporary adds :—" In the experiments at which we were present on the 7th November, the Hughes apparatus was worked at 116 revolutions, which is the normal speed of these instruments when working on overhead lines, and transmitted 50 messages of 20 words per hour, not counting service signals, and no matter what the distance was—Lille, Dijon, or Lyons. The mutual inductive action of the wires is a difficulty which is also met with in overhead lines. Transmitting apparatus always works with weak currents compared with those used with less sensitive instruments, such as the Morse. The result is that the Morse induction currents often obstruct the working of the Hughes, whilst the reverse never occurs. Dynamic induction has little influence, for it is independent of the distance, and only depends on the working current,which, as we have just said, is weak when transmitters are used. The inductive action which is most harmful is the electrostatic induction produced by the charge of one wire on its neighbour, since it increases as the square of the length of the line. The method employed on the French lines to overcome this inconvenience is very ingenious, and at the same time very practical. It consists in placing the long lines in different cables. Thus, for instance, the line of nine conductors from Paris to Lyons is composed of three cables, each enclosing three distinct conductors, one large and two small. The large conductor of each cable is in connection with Lyons, but the three direct conductors are placed in distinct cables, and consequently are sufficiently separated to prevent any but a very small amount of inductive action. The two remaining small conductors serve to connect the intermediary stations, for instance Paris and Auxerre, Auxerre and Dijon, Dijon and Lyons—that is to say, distances sufficiently small to prevent any bad mutual inductive action. The use of relays at distances of 400 kilometres, necessitated by the phenomena of charge, also limits the effects of mutual induction, and experiments made on the Dijon cable with nine Hughes instruments working simultaneously over nine wires of the subterranean line prove that mutual induction has no bad effects at this distance. As regards the influence of earth currents and great electrical disturbances in the atmosphere, such as aurora borealis, subterranean cables always allow recourse to be had to coupling up the wires so as to work over a metallic circuit entirely insulated from earth, and consequently under far better conditions than with overhead lines, the losses from which always make partial connection with earth. The big lines contain three cables of three conductors. Each conductor is composed of three strands of copper covered with three layers of gutta percha with Chatterton's compound. The conductor and its dielectric are then covered with layers of tanned jute, kept in place by an external ribbon of tanned cotton. The cables are laid in lengths of 500 meters, and the connections are made in boxes arranged at equal distances throughout the line. The use of an external protector consisting of an iron pipe affords both mechanical protection and also chemical protection for the gutta percha against the influences of the different soils traversed by the line, which it might otherwise be subjected to. The number of kilometres of wire actually laid amounts to 18,000, of which number 12,000 kilometres are at the present time in constant daily use.

The First Avenue Hotel.—At the invitation of the manager of this hotel, a number of gentlemen were present on Thursday evening to inspect this latest addition to the comforts of the travelling community. The building itself is hardly yet out of the hands of the upholsterers, carpenters, painters, and paperhangers, but quite enough has been done to show that the expenditure has been lavish in the extreme, and that every possible comfort has been provided that modern art and experience can suggest. Everything that can please the eye, minister to bodily ease and comfort, and render a stay in the hotel a pleasure, appears to have been provided, regardless of expense. However, it is not so much our province to descant upon the upholstery or stained glass windows as to describe the lighting of the building. This has been carried out by the Hammond Electric Light Company. The total number of lamps used is 1,200, all being Swan 20 candle-power, and requiring an E.M.F. of 100 volts. The distribution of these lights is as follows:—In the billiard room are 24, smoking room 24, reception room 32, entrance vestibule 20, porch 5, restaurant 60, grill room 48, library 40, grand salle 120, petite salle 32, the remainder being distributed throughout the kitchens, bed rooms, and passages, &c. The single bed rooms have one lamp on a bracket, with ground glass globe, while the double-bedded rooms have two or more lamps, according to their size. The passage lamps are attached to gas pendants in such a way that either gas or electric light can be used as required. The size of the building may be guessed when we say that the numbers of the bed rooms run to beyond 800. With the exception of the three top floors, the

Digitized by Google

whole of the electroliers and fittings have been supplied by Messrs. Verity and Sons, of King-street, Covent Garden, W.C., and the designs and workmanship are in accordance with what we have been accustomed to expect at the hands of this enterprising firm. On the ground floor, the brass-work is after the Italian and Renaissance styles, and of special designs, as at the Holborn Restaurant; it is finished in a rich gold colour, and altogether is exceedingly handsome. With such surroundings, and such fittings, the incandescent light shows to the best possible advantage. The remaining top floors have been fitted up with brackets and pendants by Mr. Hewlett, who has turned out some excellent work. His passage pendants, and the bed room brackets are very handsome. There is a switch on every floor, by means of which the lamps on that floor can be controlled, as well as a switch on the ground floor, by means of which the lamps on each separate floor can be turned off or on. With every switch is a fusible plug, to provide against any too great increase of current. The machine room is situate at the back of the building and underground. Two boilers, 27ft. long, and working at a normal pressure of 100lb., supply steam to two of Gwynne's high speed compound engines. The boilers have been supplied by Daniel Adamson, of Dukinfield, near Manchester. A Pulsometer pump is used to fill the cisterns which feed the boilers. Each engine drives one Ferranti 1,000 light machine, the plant being in duplicate to provide for breakdowns. At present only one engine and dynamo are in place, but the others will probably be up in a day or so. When these are in place it is intended to run the leads to a switchboard in the machine room, so that should any accident occur the idle engine and machine can be set to work without a minute's delay and the current from the new machine switched into the circuit. The engines will work up to 130 horse-power and makes 360 revolutions per minute, the machine making between 1,400 and 1,500. The latter is driven direct from the engine by means of two large leather belts. The dynamo is mounted on a sliding bed plate, so arranged that by turning a screw the belts can be tightened or slackened even when the machine is running. The engine is fitted with a very sensitive governor of a new type, which permits of very nice regulation of the speed. The dynamo is excited by a $D^2$ Siemens machine. The floor space occupied by the engine is very small, the bed plate being only 6ft. 6in. by 5ft. 6in. It only remains for us to mention that the work has been carried out by the Hammond Company, under the superintendence of Mr. Logan. The wiring was done by Messrs. Paterson and Cooper, who also supplied the switches, the fitting of the lamps and other details being entrusted to Mr. Reginald Belfield, of Messrs. Ferranti, Thompson, and Ince, whom we suppose we must now look upon as part and parcel of the Hammond Company.

THE DISTRIBUTION OF ELECTRICITY BY SECONDARY GENERATORS.—The National Company for the Distribution of Electricity by Secondary Generators have lighted up the stations of Notting Hill Gate, Edgware-road, Gower-street, King's Cross, and Aldgate, on the Metropolitan Railway. The system of distribution adopted by the company is that patented by Messrs. Gaulard and Gibbs, and which many of our readers no doubt had an opportunity of inspecting at the Aquarium Exhibition. The generating station is situate at Edgware-road Station, part of the Metropolitan Company's running shed being utilised for the purpose. The railway company have had a boiler and engine here for some time past, and these they have lent to the National Company to drive the generating dynamo. This latter is a Siemens W° alternate current machine, excited by a direct current Siemens dynamo. These are the only dynamos in use. The current is led direct to a secondary generator close to the dynamo, and from thence to the various stations lighted. The secondary generator is composed of 16 columns, consisting of well-insulated cable, wound round a core made up of a bundle of No. 26 iron wires. The cable contains the primary and secondary wires, the primary being in the centre and the others surrounding it. The primary wire is of No. 8 B.W.G., the secondary wires being of No. 26 B.W.G. There are 48 of these latter altogether, made up into cables of eight wires each, so that there are six of these cables surrounding the primary wire. The wires are all most carefully insulated from one another. The idea is to use the secondary current only, and to use it in such a way that by means of a commutator to which all the secondary wires are led, it is either alternate or direct, at will. The 16 columns are divided into groups of four, and the connections are so arranged that any group can be used without reference to the others. The lamps at Edgware-road comprise 25 Swan incandescents of 20 candle-power, and requiring 100 volts, and three 40 candle-power, taking the same E.M.F. There are also two Jablochkoff arc lamps, one in the engine room, and one in the railway station. We were told that the dynamo was giving nearly 2,000 volts E.M.F., and would give more. On the occasion of our visit (Wednesday evening) the incandescent lamps were burning with great steadiness, and gave a good light. Together with other representatives of the Press we visited Notting Hill Gate Station, the extent of the company's circuit in this direction, where the company have another secondary generator, 19 Swan lamps, and one Jablochkoff lamp. It was curious to notice that on approaching the generator the hum of the dynamo at Edgware-road was very distinctly reproduced. Here Mr. Gaulard ran a small motor with an alternate current from the generator, at the same time that an arc lamp and the incandescent lamps were being fed, though, of course, the circuits in each case were taken from different columns. The motor is a new one, designed by Mr. Gaulard, the patent for which is,we understand, not quite complete. Leaving Notting Hill Gate, we visited Gower-street and Aldgate Stations, at each of which a secondary generator is fitted up. The former station is lighted by 20 Swan lamps and one Jablochkoff, and the latter by 30 Swan lamps and one Jablochkoff. The company hope to have lights running at King's Cross Station by the end of this week. The wiring of the tunnels has been a work of considerable difficulty, firstly owing to the short time during which work could be carried on, viz., between 12 p.m. and 5.30 a.m., and secondly owing to the extreme dampness met with in many parts. So bad was this damp in one place, that a good deal of cable had to to be cut out and replaced by new stuff with thicker insulation. The total length of the primary circuit is between 15 and 16 miles, and the cable used is No. 8 B.W.G. The circuit is metallically closed with the dynamo, and as we ascertained for ourselves, can be touched without inconvenience at any point. The whole of the wiring was carried out for the company by Henley's Telegraph Works, the wire itself being supplied by Messrs. Walter T. Glover and Co., of Manchester. The secondary generators were made by Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, E.C., who have evidently carried out a by no means easy task with care and skill, the making of the cables with which the generators are wound, and the insulating of the wires, requiring great attention and care. The fittings have been supplied by Messrs. Patterson and Cooper, of Little Britain, E.C. Mr. Mackenzie is the engineer in charge of the work.

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 8.)

**Circumstances which Affect the Kind of Deposit.**—Both the chemical composition and the physical quality of the substances set free at the electrodes are affected by various circumstances; by the composition of the liquid and its degree of fluidity; by the strength of the current; by its density, or strength in relation to amount of surface of the electrode; by temperature, &c., and by various other circumstances.

The products of electrolysis vary also according to the kind of electrolytic arrangement employed. In the simple immersion one they are mixed with those of voltaic action. In the case of two metals in two liquids separated by a porous division, the products of voltaic action and electrolysis are largely kept separate, and in the case of electrolysis in an undivided cell by means of a separate current, the anode and cathode products become mixed.

The composition of the liquid is a fundamental condition, and variation of it has usually very powerful effects. The addition of an extra ingredient may cause entirely different substances to appear at each of the electrodes, or alter both the quantity and physical condition of the deposits. An alteration of the degree of fluidity acts similarly, but less powerfully. Whilst also with one strength or degree of density of current a single substance only may appear at each electrode, with a current of greater strength or density additional bodies not unfrequently are liberated. By either decreasing the proportion of water mixed with potassic hydrate, or increasing the strength or degree of density of the current, instead of oxygen and hydrogen alone being evolved, potassium is also set free. A weak current passing through an ordinary silver-plating liquid containing much free potassic cyanide deposits hydrogen only; but by increasing the density of the current silver is also liberated. It was by obeying these conditions that Davy isolated potassium, and Bunsen deposited chromium. Other investigators also succeeded in obtaining highly oxidable metals in the form of amalgams, without the use of powerful currents, by employing as a cathode, mercury, which absorbed the deposits, and thus largely prevented them from redissolving.

The density of the current affects also the physical properties of deposited metals. With a weak current and slow action metals are not unfrequently deposited in a crystalline state, whilst with a strong one they are thrown down as a soft black powder. A nearly saturated solution of cupric sulphate, acidulated with dilute sulphuric acid to a suitable extent, yields ductile metal when the rate of deposition is about half an ounce of metal per square foot of cathode surface per hour. The degree of density of the current not only affects the physical properties of cations, but also those of anions in some cases. Thus a stronger current is usually required to liberate ozone than to set free ordinary oxygen.

Every different metallic solution, and at every different temperature, must be electrolysed at a particular rate in order to obtain from it metal in the state of crystals, reguline metal, or black powder. Some solutions will only yield coherent metal whilst they are hot. If, also, the surface which receives the deposit varies in degree of smoothness, the physical character of the metal is affected. With a viscous solution the quality of the deposit soon changes, because the exhausted layer of liquid next the cathode is only very slowly replaced by solution containing a sufficient proportion of metal.

Different metals whilst depositing exhibit very different physical properties. Copper depositing upon the bulb of a thermometer contracts and compresses the glass bulb, and causes the mercury to rise. This phenomenon has been termed "electro-striction." Grey metallic antimony depositing very slowly until it has attained 1-10th of an inch in thickness from a solution of tartar-emetic will often crack and curl up in most fantastic shapes. Nickel when deposited to a thickness of half an inch is in the form of smooth, round knobs; copper has a somewhat similar structure when deposited from certain liquids; the knobs, however, are usually rough.

**Circumstances which Affect the Amount of Electro-Chemical Action.**—*First*, and essentially, the amount of electro-chemical effect with each substance is strictly proportional to the quantity of current, double the quantity of current liberates at the cathode double the amount of gas or metal, or causes double the amount of metal at the anode to dissolve or gas be evolved. *Second*, with different substances, it varies as their chemical equivalents, or, in other terms, it varies with the atomic (or molecular) weight and degree of valency of the substance. Thus, one atomic weight of any monad element, say silver (the atomic weight of which is = 108), requires the same quantity of current as one of any other monad element, say chlorine (the atomic weight of which is 35·5) to liberate it. One atomic weight of any dyad element, say oxygen (= 16), requires twice the quantity of one of any monad element; and one of any triad, say antimony (=122), or gold (=196), requires three times the quantity to make it electrolytically dissolve or deposit, and so on, the proportions in all cases being exactly the same as the ordinary chemical equivalents, and these may be found in any book on general inorganic chemistry. By passing an electric current through two liquids in series, one of which yielded by electrolysis pure copper only, and the other pure antimony only, I found that the weight of copper deposited was 31·7 grains, and of antimony 40·6 grains, and this agreed with one atomic weight of triad antimony or 121·98 parts, being the chemical equivalent of $1\frac{1}{2}$ atomic weights, or 95·25 parts of dyad copper. In a series of electrolysis vessels therefore, containing different liquids, and electrodes of different metals, the chemical work done by the current at any one anode or cathode is exactly equal in value to that done by it at any other of the same series in the same time. In the decomposition of water, therefore, by an electric current we obtain two parts by weight of hydrogen for each 16 parts by weight of oxygen, and in consequence of the specific gravity of the latter gas being sixteen times greater than that of the former, the relative volumes of them are as two to one. This exact relation of the quantity of the current to the amount of its chemical effect with different substances is known as the law of definite electro-chemical action, and was discovered by Faraday.

With nearly all, if not all electrolytes, Faraday's law of definite electro-chemical action is supposed to be true for even the very smallest currents. The true electro-chemical equivalent of a single substance, however, is only obtained in certain cases. In some instances a portion of the current passes through another ingredient of the liquid, and two substances are deposited simultaneously, and form the equivalent. The alteration of weight of either electrode during electrolysis is often not a true measure of current, because the metal is liable to ordinary chemical action. The true measure is the total amount of substances liberated, taken before they have had time to suffer ordinary chemical change.

**Influence of Temperature, &c., on Electrolysis.**—Change of temperature has a great effect. Both the electric conductivity and the diffusive power of saline solutions increase by rise of temperature, and each of these circumstances greatly promotes electrolysis. Rise of temperature affects also the relative proportions of current conveyed by the different ingredients of a mixed electrolyte; for instance, I found that in the electrolysis of an acidified solution of cupric sulphate with copper electrodes a considerable deficiency of deposited copper, sometimes amounting to as much as 16 per cent., may result through employing a *hot* solution. ("Electrolysis of Sulphate of Copper," *Proceedings of the Birmingham Philosophical Society*, Vol. III., p. 75; *The Electrician*, Vol. VIII., pp. 271—280). Very few experiments have as yet been made on the influence of great pressure (*see* Section 48) or of magnetism on electrolysis. Remsen, however, found by depositing copper from a solution of cupric sulphate contained in a thin vessel of sheet iron, placed upon the pole of a powerful permanent magnet, that the deposit occurred in a fairly uniform way on the entire surface of the iron ex-

Digitized by Google

cept at the parts marking the outlines of the poles. These lines were strongly marked as depressions in the copper. The action was still more striking when an electro-magnet was used instead of the permanent one. In a narrow space marking the outline of the pole there was no deposit. Within this line it was fairly uniform, but outside of it the copper aggregated in irregular ridges, running at right angles to the lines of force, and apparently coinciding with those marking the equipotential surfaces.

**Relations of Electro-Chemical to Ordinary Chemical Action.**—Electrolytic changes obey the same law of equivalence of action, as ordinary chemical ones, and electro-chemical action by a separate current may be viewed as ordinary chemical action taking place in one large and measurable circuit instead of in a multitude of excessively small and non-measurable ones, and conversely, ordinary chemical corrosion of metals in electrolytes may be viewed as electro-chemical action taking place in an infinite number of such minute circuits.

The electrolytic circuits in which electric currents flow may be of any degree of magnitude, from these small ones upwards, and such currents, of various degrees of magnitude, may circulate simultaneously in the same metals and liquid. Electro-chemical action, therefore, does not necessarily exclude ordinary chemical change. One large current may flow through the electrodes and liquid of an electrolytic cell, whilst "local" action (*i.e.*, ordinary chemical action in patches) in lesser circuits is taking place upon each of the electrodes, and also whilst ordinary chemical action is occurring uniformly upon them.

When an electric current is passed through an electrolyte, whether attended by corrosion of the anode or deposition of metal upon the cathode or not, the layers of liquid in contact with each electrode become changed in chemical composition and density, and are thus indirectly set in motion by the influence of the current, and in consequence of this the ordinary chemical action upon them is altered. In some cases alkali collects around the cathode, and acid around the anode, in others the liquid around the former becomes more dilute and ascends, whilst that around the latter becomes more saturated with salt and descends. In others, again, insoluble gas is evolved from each electrode, and causes an upward motion of liquid, and in others the gas dissolves in the liquid and alters its degree of corrosive power, as well as of specific gravity; and in some of these cases, by increasing the density of the current up to a certain point, the ordinary chemical action of the liquid upon the cathode is diminished until all such corrosion ceases. This point I have termed "the electrolytic balance of chemical corrosion," and have investigated it in the case of silver in an ordinary cyanide plating solution (*see Proceedings of the Birmingham Philosophical Society*, Vol. III., pp. 268—305, also an abstract in *The Electrician*, Vol. X., p. 381). Many other cases in which ordinary chemical corrosion is balanced and prevented by electro-chemical action remain to be investigated. In some cases the rate of corrosion of a cathode is increased during electrolysis, in consequence of the evolution of hydrogen and consequent motion of the liquid bringing fresh corrosive particles into contact with it (*see* "Corrosion of Cathodes," *Proceedings of the Birmingham Philosophical Society*, Vol. III., p. 305; *The Electrician*, Vol. XI., p. 213).

(TO BE CONTINUED.)

THE FORTH BRIDGE.—Last week the electric light was in operation at the Forth Bridge works for the first time. The only part of the installation yet completed is that for the lighting of the work-sheds, in which there are sixteen lamps. So far it appears to be very successful, as every article in the sheds, from one end to the other, could be clearly discerned. A number of lamps have been erected outside these sheds, as also within the drawing-sheds and offices, and are expected to be in operation in a very short time. Those on Inchgarvie and at North Queensferry are also nearly completed, and are expected to be in operation about the same time.

## THE EVOLUTION OF DYNAMO MACHINES.—II.

BY JOHN T. SPRAGUE.

(CONCLUDED FROM PAGE 9.)

14. We must now trace out another line of evolution, which, though apparently distinct, is yet of the same order as the one examined, though relating to the wire in which currents are produced instead of to the form of the inducing agent. The action of wires crossing lines of force appears to be different from that of wires wound upon a bar of iron temporarily magnetised; but the currents produced in both cases are due to the absorption of external energy, and to the re-arrangement of the molecules of the wire while adapting themselves to the lines of force which they momentarily occupy. The difference is that in one case the wires form part of the magnetised system itself, and in the other they temporarily form part of an independent system.

15. *No particle of matter is independent or isolated.* This is a fact so rarely dwelt upon that it is of great importance to true thought that it should be thoroughly realised and firmly grasped by the mind. Nothing in nature exists by or for itself, but is related to, influenced by, and influencing all its surroundings. Every atom of matter is in the place, and, under the conditions it occupies, as a result of the sum of the various forces which influence it. We know that the universal force of gravitation is the evidence of this mutual relation of every particle of matter in the universe. The constant balancing and fluctuation of the various forces is most strikingly evidenced by the infinitesimally instant molecular changes and motions which we have traced out of late years. The sounds given out by many forms of matter, under rapid intermittence of light and heat, are due purely to such motions resulting from the rapidly-changing forces to which the molecules are subjected.

16. Thus, in a wire, each molecule is itself constituted of two distinct atoms, held together (probably by polar forces analogous to those of magnetism, though commonly attributed to differential + and − electrifications of the atoms) by the force called "chemical affinity," or attraction. This force may be regarded as an allotropic form of E.M.F., as shown in the paper on "Potential, Current, and Resistance," p. 319, Vol. XI. The mass of the wire is held together by similar forces of molecular attraction, crystallisation, and cohesion. All these forces imply energy stored in the matter, and are modified from moment to moment by heat and other external forces, and they, no doubt, all hold the relation to electromotive force (formulated Section 35 of the article referred to, p. 318), of potential energy seeking to become kinetic, and enabled to do so as electric current when proper conditions arise in a closed polar molecular circuit. *The actual arrangement of the molecules of the wire is the combined result of all the forces influencing them at any instant.* They are in a state of equilibrium, liable to instant change

17. Such a change occurs the moment the wire enters a "field of force," the energy of which is charged upon its molecules and introduces new conditions of balance. The excess of force, the new stresses set up against the pre-existing internal forces, involve an expenditure of energy in effecting the necessary rearrangement of the molecules, and thus we have the conditions defined in Section 35, p. 318, already referred to. The potential energy of the lines of force in the field, or the energy necessary to force the molecules of the wire into these lines, becomes kinetic in the wire, and therefore develops E.M.F., and, in effecting motion among the molecules of the wire, generates an electric current according to the arrangement of these molecules—the number of conducting chains which they can constitute. Therefore, in order to generate a current, the wire must so traverse a field, or be so related to the forces, as to continually change the arrangement of its molecules, and their relation to the sum of the actions exerted upon them. Mere motion in a field may produce no effect whatever.

18. When a pole of a bar magnet is inserted into a ring of wire carrying a current, a reaction occurs between the two fields which, if concordant, tends to unite them into one, and as a consequence to place the two centres of the fields together. If discordant, that is, if the lines of force are not

Digitized by Google

in the same direction, a sort of conflict occurs for the possession of the space and matter in which the lines of force exist. In the first case we have *attraction*, and the ring of wire moves to the central plane of the magnet, because there the field of the magnet and that of the wire coincide, and have the highest mutual action upon each other. In the other case we have what is called *repulsion*, because each field seeks the area of greatest capacity for its lines, and therefore they are drawn to positions in which they cannot interfere. The current in the wire is also increased or diminished during the action.

19. When a bar magnet is inserted into a ring of wire not occupied by a current, it sets up a momentary current therein, *opposite in direction to the proper magnetising current of the bar;* a mechanical resistance to the pressure is also experienced, and the ring is for the moment repelled. These actions are examples of Lenz's law, that "the direction of the current (or generally of any action) set up by any motion will be such as will resist that motion." But it is not enough to refer to a law, as lawyers may to the "Act in that case made and provided," we should realise what is the cause and the process. In this case the wire becomes a part of the *external* field of the magnet, and therefore as it enters into lines of force of reverse direction to those of the magnet itself, the consequent electric wave is in the reverse direction to that of a magnetising current, which is part of the *internal* lines, an integral part of the magnet.

20. In order to make these mutual reactions clear, it may be well to examine somewhat closely what takes place in magnets and conductors. In a conducting wire there is a molecular action which we may consider as an impulse, or a wave, or rotation transmitted from molecule to molecule in a definite chain originating at the point where the E.M.F. exists, and travelling in both ways thence to a point of union, the action on the two sides of the point of origin being of opposite characters. But besides this internal action and motion there is an accompanying action upon external space which induces static stresses in that space, and these stresses are of two orders, longitudinal and radial. There is the stress of static electric induction from every part of the conductor to every other part, which may be considered as forming a sheath of lines of force parallel to the conductor. There is also the magnetic charge at right angles to all the electric lines, and therefore resulting in circular fields around the conductor. Not only do magnetised needles place themselves everywhere tangentially to these circles (which really means that they place themselves as much as possible in the circles), but the resulting magnetic rings may be made visible.

21. If we pass a current-carrying wire through a card upon which iron filings are sprinkled, and tap the card lightly, the filings arrange themselves around the wire, thinning away as distance increases; they are, in fact, temporarily magnetised, and unite lengthwise to form closed rings around the conductor in the lines of equal magnetic force. It should be clearly understood that these rings have no polar properties

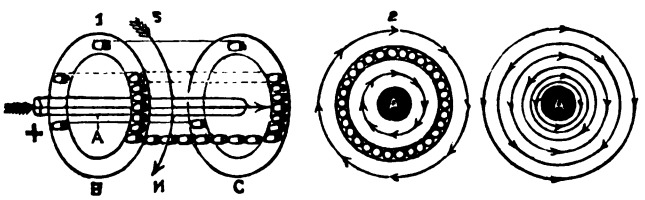

Fig. 8.

or attractions; they resemble a closed steel ring, which may be strongly magnetised yet have no apparent magnetism, because it is a completely closed field; at every section there is an equal N and S pole existing and combining together. It is true that a piece of iron, such as a filing, enters the ring and does then possess two poles, because its capacity is greater than that of the air; but these poles are purely *within the ring;* they exert no external actions, because the iron is not an independent magnet, but only a part of the external lines of the wire, and therefore its poles are related only to the wire. Fig. 8 is intended to convey the idea of a conductor and these external inductions: 1 shows a perspective view; A, as the conductor and its arrow, +, shows the direction of the current; B and C are two rings of magnetic force, consisting of molecules polarised under longitudinal forces, shown by the dotted lines connecting the circles B C, these lines representing the stresses due to difference of potential set up in the polarised chains constituted by static electric induction, of which one chain is shown connecting the rings. Parts 2 and 3 of Fig. 8 are sectional views, showing B C, of which 2 illustrates the molecular construction and 3 conveys simply the idea of the lines of magnetic constitution.

22. A closed magnetic ring, when cut across, manifests true poles at which the forces are constituted, and a similar effect can be produced in the circular lines of force around a conductor. This happens, in fact, when the wire is wound into a helix, forming a series of rings of wire side by side, as is shown in Fig. 9. It should be remembered that these figures are no mere fancy; the iron filings prove their truth if we pass several wires through the card as before described. In Fig. 9, 1 represents the conditions of a single ring of wire, the unit turn of the helix; in fact, it is the conductor A of Fig. 8 turned into a ring, so as to bring all its lower side into the inner part. Then it is evident that all its rings of force tend in the one direction internally, and in the opposite direction externally. The internal arrow shows the resultant magnetic action as though these rings constituted an internal vortex.

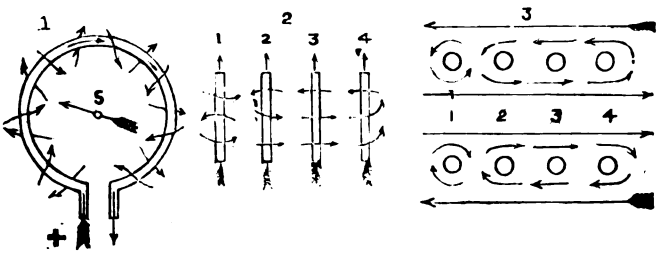

Fig. 9.

23. A series of such rings placed side by side is shown in Fig. 9, in vertical section at 2, which represents the further or left hand side as looked at across the interior. It should be noted that the change in direction of the small arrows from those in the earlier figures is the result of looking at the rings from the other side, as is evident in all three portions of this figure. In 3, which is a horizontal section of the helix, we see that the circular lines of force of the adjoining wires conflict as they enter each other, and are therefore broken up into their external and internal halves, which then unite to form lines of force along the whole of the wires.

24. Fig. 10 illustrates the way in which the different modes of winding wires bring these principles into action.

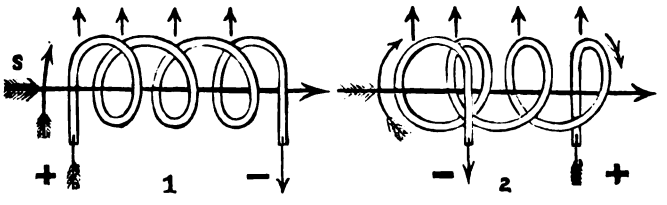

Fig. 10.

1 is a dextrorsal or right handed helix, in which the wire (and the current as shown) follows the direction of the hands of a watch. The internal arrow, representing a magnet bar, shows the law of direction of magnetism, viz., *a current* (from the + pole) *moving as the hands of a watch*, viz., from the left upwards over the core, *gives south magnetism* within it *on the face looked at*. It gives north magnetism on its *exterior*. A reverse current gives reversed polarity. The *left handed* or sinistrorsal helix is shown Fig. 10, 3 arranged to give similar polarity, by reversing the direction of the current; in fact, as arranged it represents the continued return winding

Digitized by Google

of the wire of 1. In this way it is evident that the direction of the current *in each turn of wire* is the same in both cases, the whole of the currents throughout being parallel.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 14.)

The short beam supporting the bottom brake block should be rigidly guided, so as to avoid that, by a lateral movement, the blocks be jammed tight on to the pulley. It was to prevent this that Poncelet modified the Prony brake by making the top and bottom beams bow-shaped, and of equal length, and also by extending them symmetrically to the other side of the shaft. The tightening screws were placed at the end of the beams, and thus a somewhat elastic pressure between brake blocks and pulley was obtained. Poncelet also altered the manner in which the brake was weighted. By referring to Fig. 2, p. 14, it will be seen that if the beam rises the leverage R of the weights P becomes somewhat diminished, whilst if it sinks the leverage becomes increased. The brake is therefore in unstable equilibrium. To make it stable Poncelet attached the weights not directly to the beam, but to the lower end of a vertical rod, the upper end of which was rigidly fixed to the beam. By this arrangement a rise of the brake will produce an increase, a fall of it a decrease of leverage, thus rendering the apparatus steady. The same result can also be obtained by reversing the position of the brake shown in Fig. 2, so that friction on the blocks tends to depress the end of the beam, the balancing weights being hung over a pulley, as shown in dotted lines. The same arrangement can also be used to balance, and then eliminate from the calculation the weight of the beam itself, which should always be done before using the brake. Let F be the pressure and $\phi$ the co-efficient of friction between the face of the pulley and the brake blocks, then the twisting momentum which tends to carry the brake round with the shaft is

$$T = 2 \phi F r.$$

This must be balanced by the weight P acting at the distance R from the shaft

$$P R = 2 \phi F r.$$

The work destroyed in friction is found by multiplying the pull on the face of the pulley with its velocity. If the shaft makes $n$ revolutions per minute, the distance travelled by the surface of the pulley in that time is $2 \pi r n$, and the work absorbed in foot-pounds per minute is

$$W = 2 \phi F 2 \pi r n.$$
$$W = P 2 \pi R n.$$

$2 \pi R$ is the circumference of a circle which would be described by the weight P if it were allowed to go round with the shaft, and $2 \pi R n$ is the distance in feet the weight would thus travel per minute. Imagine a drum of radius R fixed on the shaft and the weight P hauled up by means of a rope coiled on this drum, then the work done in raising the weight would be exactly equal to that used up in friction by the brake. It is important to note that neither the diameter of the pulley, nor the pressure of the blocks, nor the co-efficient of friction, enter into the equation for the work absorbed. The only data we need know are length of lever R in feet, weight P in pounds, and speed of shaft in revolutions per minute. The horse-power absorbed is then found by using the formula

$$\text{H.-P.} = \frac{1}{33000} P 2 \pi R n.$$

It is of great practical importance to know how much power a given brake can conveniently absorb. The work is partly transformed into heat, and partly used up in destroying the surfaces in friction. The latter item must evidently be very small if the brake is to run for a long time without giving trouble, and therefore all, or nearly all, the power absorbed should be dissipated in the form of heat. The capacity of a body for dissipating heat depends on the extent of its surface, and the difference of temperature between that surface and the surrounding air. If the body and the air be relatively to each other at rest, the layers of air nearest to the surface become themselves elevated in temperature, and the cooling of the body can only take place very slowly. But suppose we renew the air or shift the position of the body from time to time, then a greater difference of temperature can be kept up and the body will be able to dissipate more heat. The more often we change the air, or the quicker we move the body through it, the greater will be the quantity of heat which it gives up to the air, so that we may assume the capacity of a pulley to dissipate heat to be, roughly speaking, proportional to its speed as well as to its surface. From this it follows that the work which can safely be used up in friction on the surface of a pulley of radius $r$ and width $a$ will approximately be proportional to $2 \pi r a n = v a$, where $v = 2 \pi r n$, the circumferential velocity of the pulley face in feet per minute, and $a$ its width in inches.

The exact ratio between horse-power and $v a$ is purely a matter of experience. It depends on a variety of circumstances which are quite out of the reach of calculation, as, for instance, material of pulley and blocks, lubricants, temperature of the air, and even skill in using the brake. Generally speaking, a plentiful lubrication, and even cooling by water, will enable a brake to absorb larger powers than if lubricated by suet or tallow and only cooled by air; but the use of water, especially when testing electric machinery, is so troublesome that in most cases it will be found more convenient to use a rather larger brake lubricated by some fat. As a good practical rule to find the size of brake required Mr. Maw's formula can be used as given in *Engineering* of 21st July, 1876, page 61. According to this rule the speed of the pulley face in feet per minute multiplied with the width of it in inches and divided by the horse-power should not be less than 700.

$$\frac{v a}{\text{H.-P.}} \geq 700.$$

A very handy and portable brake, designed and manufactured by Messrs. R. Hornsby and Sons, is shown in Fig. 3,

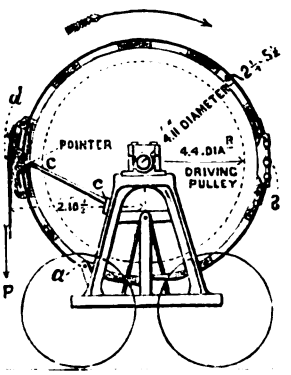

FIG. 3.

for the drawing of which the author is indebted to the firm's engineer, Mr. R. Edwards, M.I.C.E. The base plate is mounted on wheels, and carries two A frames with bearings for the shaft. On the latter are keyed two pulleys, one for the belt from the engine to be tested, and the other for the brake band, which is made of flat steel, furnished on the inside with wooden brake blocks. The band surrounds the pulley entirely, and can be tightened up by means of a right and left-handed screw, $s$. The weights are attached to a hook diametrically opposite the screw, and when equilibrium is obtained a pointer, $d$, fastened to the band must come opposite a fixed pointer carried on the arm $c c$. The bolt $a$ is rigidly fixed to the base plate, and passing between pulley and steel band in one of the clear spaces between two brake blocks limits the movement of the brake to one side and the other. The lubrication is by suet or tallow, which is placed into the corners formed between the face of the pulley and the upper brake blocks, and

Digitized by Google

renewed as required. This brake will work perfectly cool at 20 horse-power and 150 revolutions, requiring very little attention. It should be noticed that Hornsby's brake has neither dashpot nor any contrivance for rendering its equilibrium (which is indifferent) stable. But in spite of this it runs very steadily, a fact which is perhaps due to the large size of the brake pulley in comparison to the power it is called upon to absorb. A brake similar in appearance, but with a very ingenious arrangement for making its equilibrium stable, is I. Imray's brake. Advantage is here taken of the relation existing between the friction of a band round a pulley and the arc embraced. The larger a portion of the circumference is actually in contact with the band the greater is the friction. In Fig. 4, *a b c* is the brake band touching

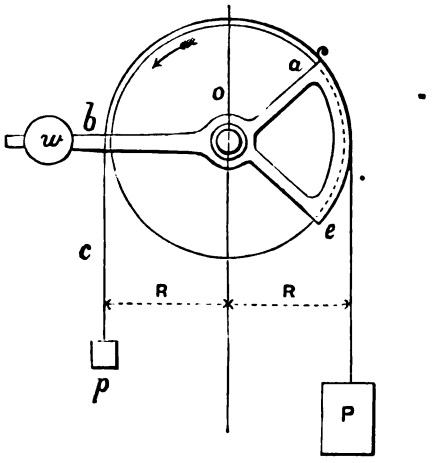

Fig. 4.

the pulley only over an angle *a o b*. The weight P is attached by means of a flexible band, *a d*, which does not touch the brake pulley at all, but lies over a cast-iron segment, *a o e*, curved to the same radius as the brake band proper. This segment is counterbalanced by a weight, *w*. A small weight, *p*, is applied to the slack end of the brake band to keep it vertical and up to the pulley at *b*. It is easy to see how this arrangement acts. Suppose the brake were too lightly loaded, then the weight P, and with it the cast-iron segment, would rise, thereby lessening the angle *a o b*, and consequently also the frictional pull on the brake band which has drawn P up; on the other hand, if the weight were to sink, the angle *a o b* would become greater, thereby increasing the grip of the pulley on the brake band until equilibrium is again established between the frictional pull and the weight. To calculate the work absorbed by this brake the same formula as given for the Prony brake must be used; but instead of P insert $P - p$.

## SUBMARINE MINES.

(CONTINUED FROM PAGE 561.)

*Dynamo-Electric Apparatus.*—This class differs from the magneto-electric apparatus, just described, only in the use of electro-magnets instead of permanent magnets to maintain the magnetic field of force requisite to the development of the electrical currents. In other words, with dynamo machines physical power is employed to generate both the magnetism and the electricity. The chief advantages of these machines are that they are not liable to deteriorate from the gradual loss of the permanent magnetism, and that with equal weight they can be made far more powerful. On the other hand, they require more physical force. Their action is certain, because the core of an electro-magnet always retains a slight residual charge of magnetism. The feeble waves of electricity developed by the movement of the armature in this feeble field of force are, if alternating, first caused to move in the same direction by the use of a commutator, and then are passed through the wires enveloping the cores. The intensity of the magnetic field is thus increased, and by mutual action and reaction it soon becomes exceedingly powerful.

One broad distinction between instruments of this class is based upon the mode adopted for maintaining the field of force. Sometimes, as in the Ladd and Hochhausen machines, a certain part of the electrical current is exclusively devoted to this object, the design being to produce a uniform field whatever be the resistance of the working circuit. With such instruments this object will be attained, and the electromotive force will depend solely upon the speed of revolution, and be independent of the resistance of the external circuit only when a magnetising current is employed strong enough not only to saturate the cores of the magnets *per se*, but also to overcome the reaction of working currents circulating through the working armature which tend to reduce the intensity of the field of force, and hence to cut down their own strength. With a small external resistance this reaction may be very strong; and, as a matter of fact, both of the machines named fail to accomplish the result intended when the external resistance is very small. With this kind of apparatus the electromotive force is an *increasing* function of this resistance.

With certain other instruments, the windings of the field of force magnets form part of the general working circuit, and in this case a strong field, and hence a high electromotive force, is only possible when the resistance of the exterior circuit plus that of the windings is not sufficient to cut down the current below the strength requisite to maintain magnetic saturation in the cores. Here the electromotive force is a *decreasing* function of the external resistance.

For igniting apparatus, a compromise between these two systems is common. The current is first caused to circulate only through the windings of the cores, and, when the latter become saturated, it is switched suddenly into the exterior or working circuit containing the fuses. The effect is very rapidly to cut down its strength, but in the meantime the fuses have exploded, and hence the desired work is accomplished.

From another point of view, dynamo-electric machines may be classified according to the form in which the electrical force is utilised. Thus these instruments may act: (1) by a single wave, strong at first, but rapidly losing power; (2) by a succession of waves alternating in direction; (3) by a current more or less unvarying. By the use of a commutator an alternating current may be transformed into one pulsating in a single direction, thus transferring the instrument from from Class (2) to Class (3).

The following tabular classification, based on this analysis, includes the igniting machines now in most common use:—

| | |
|---|---|
| I. Acting by a diminishing wave..... | Siemens spark.<br>Farmer.<br>Smith.<br>Lafflin and Rand. |
| II. Acting by a succession of waves, alternating in direction ..... | Ladd, without commutator. |
| III. Acting by a continuous current | Siemens current<br>Ladd, with commutator.<br>Hochhausen.<br>Gramme. |

Of these machines, Siemens's spark can be used with either high or medium tension fuses. Ladd without commutator, only with medium tension fuses; all the rest are specially designed for low tension, but some of them may be employed with medium-tension fuses.

A brief description will now be given of these instruments and of their tests.

*The Siemens Spark Machine.*—This machine (Fig. 6), acts upon the principle that soft iron always retains a weak residual charge of magnetism, a fact discovered by Siemens.

Digitized by Google

It is operated by a horseshoe magnet, which being of soft iron retains only a small magnetic force when not in action. The bars are wrapped with 1,000 ohms of insulated wire, No. 23 B.W.G. When a powerful current of electricity flows through this wrapping, a strong magnetic power is of course developed thereby in the bars. The poles are 4·5in. in length, and nearly envelop between them what is known as a Siemens armature. This consists of a bar of soft iron 4·5in. long and 2in. in diameter, grooved longitudinally, and wrapped in this groove with ·2 ohm of rather coarse wire. This armature is pivoted at its extremities, and connected by suitable gearing with an external crank, by which a rapid revolution can be given six turns to one of the crank. The ends of the armature wrapping are attached to the opposite sides of a commutator on one end of the armature bar. Springs connected with the ends of the magnet wrapping touch first one and then the other of these terminals at each revolution of the armature, and thus convey the current generated by the revolution of the armature within the magnetic field, thrown into the same direction by the commutator through the magnet coils. When the revolution begins this current is feeble, but as the strength of the magnet increases the latter reacts, and thus strengthens the current, which in its turn still more strengthens the magnet. Thus in a few seconds both magnet and current become very strong, as is made evident by the increased power required to turn the crank.

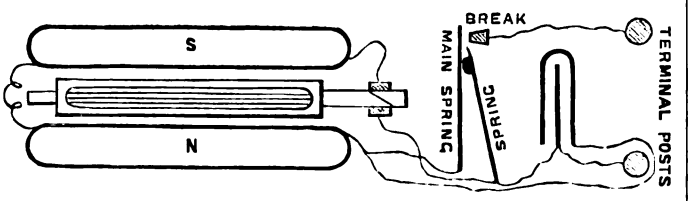

Fig. 6.—Siemen's Spark Machine.

To utilise this current, a wire passes from one of the springs to an external binding post, touching *en route* one of the plates of a small condenser, ·002 microfarad in capacity. The wire from the other spring, after traversing the coils of the magnet, is attached to the other plate of the condenser, and also to a mainspring, and through it to a brake, which, when mechanically closed, extends the circuit to a second external binding post. This brake is regulated by an ingenious device attached to the driving shaft, which, after two turns of the crank, releases the mainspring, and through its agency closes the circuit to the binding post, and instantly after opens the short circuit through which the current had been flowing. The effect is to send through the external circuit a short wave, due to the current and a strong extra current, reinforced by the condenser.

This machine is encased in a box 14 by 7 by 13in., the the weight of the whole being 52lb. It requires a high or medium tension fuse, and throws a spark of large quantity and of comparatively low potential. This feature renders it especially fitted for use with good submerged cable, as electrification does not rapidly reduce the volume of the spark below the effective limit. An Abel fuse can easily be exploded by it through a submerged circuit of a couple of miles of good torpedo cable, use being made of the earth for a return circuit. Twelve Abel fuses, connected in series or in multiple arc, can be exploded in a short land circuit.

From the manner in which this instrument discharges itself through the fuse circuit, it seems altogether improbable that the ratio of the times in the equation [given in p. 426, Vol. XI.] can be regarded as unity in comparing its strength of current with that of the magneto-electric machines acting by a single wave; and hence that method cannot be safely trusted. As a matter of curiosity, however, the attempt was made; and the result developed the fact that it is exceedingly difficult to obtain uniform discharges. The maximum time in which to excite the magnets is limited by two revolutions of the crank; and this is not enough. Successive trials gave discordant swings to the needle, indicating a range of ten per cent., even when every care was taken to obtain a maximum. The average strength of current seemed to be about 1·5 times larger than that of the Marcus machine, or perhaps about 1,300 microfarads; but, for the reason above stated, no precision can be claimed for these figures. In using the instrument care must be observed to *begin the revolutions with the crank in the position where the mainspring has just acted*, and to turn as rapidly as possible. If these precautions be neglected much power will be lost.

(TO BE CONTINUED.)

## LITERATURE.

*The Modern Applications of Electricity.* By E. Hospitalier. Translated and enlarged by Julius Maier, Ph. D. Second Edition. In two vols. [Kegan Paul, Trench, and Co.]

This is a work which proves that anything pertaining to electrical literature will sell. The translator has in a hundred ways shown a bias against the electrical literature which has appeared in the English language, and imagines that we may be deceived in appraising the value of hack work. To criticise the work means to criticise articles which have appeared in periodicals, some at first hand, most at second and third hand, and from sources which have evidently not been brought into contact with the apparatus described. Let us take an example or two. Why should *La Lumière Electrique* be credited with Kempe's electric water gauge? The first description of that apparatus, we imagine, appeared in an English contemporary, as did, we imagine, the illustration of Jacobi's electric motor for vessels. Mr. Kempe himself perhaps could tell us about the former, Professor S. Thompson about the latter. May not the same be said of the motors on board the "Electricity?" The translator has gone out of his way to give great prominence to our French contemporary. He has even credited it with illustrations obtained from another source, and has avoided giving anything like so much prominence to English work. Now, we do not deny for a moment that *La Lumière Electrique* is a publication deserving the highest praise, but we do object, and emphatically so, to the manner in which Mr. Maier puts forward what is too frequently merely a translation of a translation. Thus, on pp. 199 and 201, Vol. II., we get diagrams of Liveing's apparatus. Unless we are in error Messrs. Latimer Clark, Muirhead and Co. issued an illustrated pamphlet descriptive of this apparatus at the Paris Exhibition, yet we feel certain that most readers will take it for granted that the illustrations and description are due to our contemporary. We should not have made these remarks if our contemporary had been credited with its admittedly excellent work in the same general manner as others have been credited in the preface.

The general plan of the work is simple. The work of M. Hospitalier forms the groundwork of the first volume. The remaining portion of the first volume, and the greater part of second volume, consists of translations or abstracts of articles which have appeared in contemporary literature—mainly, indeed, from *La Lumière Electrique*. We think such a work is useful. It gives in a compendious form descriptions of apparatus that would otherwise be found only after considerable trouble. The work of a compiler is by no means easy. The matter to hand is so large that it is difficult to make a selection. To appraise the value of the work we must put ourselves in the place of busy men who wish for a general knowledge of electrical progress, but who have no opportunity of following it closely. Such a work as this appeals to them. Herein they find little theory, plenty of simple description, and illustrations of the most modern apparatus. What we complain of is the impression left on the reader's mind that, both in the matter of illustration and of literary exposition, the French electrical journals are to be credited with everything and the English with nothing; this is not fair, and it is certainly not true.

## LOSSES TO ELECTRICAL SCIENCE.

The electrical world has sustained some very serious losses during the present year, but none that has been at once so serious and so surprising as in the person of Sir William Siemens. Both Sir Edward Sabine and Mr. Spottiswoode, whose deaths we had to record only a short time ago, were long past the prime of life; and in the case of Mr. Varley, whose health was known to have sustained some severe shocks in recent years, there was nothing startling in the announcement of his having finally succumbed. Mr. Werdermann was a younger man, and an electrician of great promise, but his loss attracted comparatively little attention, although to those who knew him the labour of his life seemed to have deserved a better recognition at death. But in Sir William Siemens there was combined well-deserved popularity, high distinction in scientific circles, with, to all appearance, a robust frame. His cheery manners, his healthy smile and confident bearing, all betokened a man who, although past the prime of life in years, was enjoying both intellectually and physically the advantages of faculties at their best. The accident which happened to him a fortnight ago excited no apprehension at the time, and we are now only echoing the surprise which is being expressed on all hands that a life apparently so vigorous should have been cut off so unexpectedly and so prematurely.

Tuesday evening's papers, which announced the removal of this well-known name from the list of leaders of modern science, also told us that the Society of Arts had postponed its opening meeting on Wednesday in consequence of the death of the chairman of the council of the society. Sir William Siemens, better known as Dr. Siemens, was foremost in promoting such work as that with which the Society of Arts is closely identified, and his loss in that and in similar spheres elsewhere will be much regretted. But in the higher walks of science his death will be felt perhaps even more acutely. He was the representative, probably the ablest representative, of what may be called the modern school of scientists who strive to unite the practical and theoretical sides of science into one consistent whole. In his own person he was eminently fitted to represent this union. His speculations in physical astronomy showed that in the region of theory, or as some people may prefer to call it, of fancy, his imagination was both fertile and daring; whilst his vast store of practical experience in the everyday application of theroetical science to the requirements of enterprise and commerce placed him at the head of all practical men. The views publicly put forward by him on the several occasions when this or that side of his nature was being revealed may have been open to criticism, and the recommendation of them to others as a possible and even necessary combination in workers of ordinary capacity may have been objected to on grounds of practicability; but nobody will deny that he was a conspicuous example of the possibility of combining the practical and theoretical in one person, and of shining pre-eminently with both.

It is difficult to recall the bereavements of the present year without a feeling something akin to consternation. We have men still left among us, it is true, well qualified to sustain the extra burdens and responsibilities which the stroke of death has laid upon their shoulders; but for the moment we can only think of those whom the dread hand has removed—the hand which science can but seldom delay, and is utterly powerless to disarm. Five such men as those we have named disappearing from our midst within the space of a few short months is enough to sadden and almost to dispirit us. In the electrical world especially this is the case. Four of them, Spottiswoode, Varley, Sabine, and Siemens were Fellows of the Royal Society, of which the first was for a time its president. Both he and Sir William Siemens had also the destinction of being presidents of the British Association, and the latter was on two occasions elected President of the Society of Telegraph Engineers. Spottiswoode, although professionally a mathematician, was an eminent electrician, and his name, as well as the names of those other four who were more closely associated with electrical matters, must be included in the death roll of electricians for the year 1883. We cannot recall any period of past history when the losses to one special branch of science have been so serious or so numerous.

It will redound to the credit of the man to whose memory we are addressing these few inadequate words that his name is not left associated with impracticable schemes or speculative adventure. At a time when electric lighting has offered the greatest temptations to scientific and practical minds to humour popular delusions, his attitude has been uniformly

Digitized by Google

calm and straightforward. As confident as the most sanguine of the ultimate triumph of electricity over gas and over steam, he has never pretended that these triumphs are already achieved, and although one of the highest of authorities when living of the practical possibilitiee of electric lighting and electrical dynamics, we are much mistaken if any one will have reason to regret that his opinion ever led them astray, or that his example ever induced them to risk money where there was no probability of its being profitably laid out. If anything will reconcile his friends to his untimely loss it will be the memory of a stainless life, and the honourable as well as distinguished name he has left behind him.

## SIR WILLIAM SIEMENS.

When the death-roll announces the fall of a field-marshal the flags are down, and every rank and file is struck with sorrow and awe! The army of workers in scientific and practical researches, nay, the whole country and the entire world, have just lost one of their principal leaders, who fought many a battle for the improvement of scientific processes, and who carried many victories with him, by which he not only endowed the world with new knowledge and new power, but he thereby also ameliorated the condition of thousands of the working classes by finding them permanent employment.

It is with the deepest regret that we have to announce the sudden death of Sir William Siemens, which occurred on the evening of Monday last, the 18th inst., in consequence of an injury to the heart, brought about by a fall a fortnight previously. Walking home from a scientific meeting on the afternoon of the 5th inst. he fell while crossing Hamilton-place, and it was soon found that the heart had been injured. There seemed to be no reason to fear a fatal result, till on Monday last, quite suddenly, the end came.

It would be vain to endeavour in a brief sketch to do justice to the career of one of the most remarkable practical scientific men of the age; and what we say can only do scant justice to him in whom were combined in a remarkable degree depth and thoroughness of study, with a wonderful amount of varied inventive genius and versatility. His name can never be forgotten in almost any of the walks of science or manufacture. Every one of his discoveries added to the prosperity of the country.

Carl Wilhelm Siemens, descending from an old patrician German family, on whose coat of arms the motto, "Through energy to success," stands engraved, and which the deceased so ardently carried out for the enrichment of the world, was born at Leuthe, in Hanover. He was educated at the college at Luebeck, afterwards at the Polytechnic School at Magdeburg, and finally at the University of Gœttingen, where he had the advantage of laying, under the guidance of Professors Woehler and Himly, the foundation of that knowledge in mechanics, chemistry, and physics, which he had ever since so well applied to useful results. In 1842 he became a pupil in the engine works of Count Stolberg, and in 1843 he came to England for the purpose of introducing a method of gilding and silvering by galvanic deposit, principally the invention of his elder brother, Dr. Werner Siemens. He returned to Germany, and in 1844 came again to England to patent a differential governor for steam engines. The four brothers, Werner, Wilhelm, Carl, and Friedrich, all worked so harmoniously together, and were always so ready to attribute a successful invention to any of the family, that in many cases it becomes rather difficult to say what is the precise personal share of each of them.

After having decided, in 1844, to remain in England, he brought out the anastatic process of printing, which was afterwards described by Faraday in a lecture before the Royal Institution in 1845. He then was variously engaged upon railway works, calico printing, and his chronometric governor, which came into use at the Royal Observatory at Greenwich for controlling the motion of transit and recording instruments.

In 1846 was introduced the double-cylinder air pump, and in 1847 he turned his attention to the dynamical theory of heat and invented a regenerating caloric engine. But it was owing to his studies and experiments in the dynamic theory of heat that he was led to the invention of his world-renowned regenerative gas furnace, which was produced in the year 1848, and is one of the most interesting records of practical science. For the long period of twenty-three years did he persevere in experimenting and improving the regenerative furnace, until complete success at length crowned his efforts, and he became known as the manufacturer of the Siemens steel, produced on an open hearth—a process which has done a great deal to facilitate the substitution of steel for iron in the manufacture of ships and boilers.

A regenerative engine, using superheated steam, was also constructed, and was awarded a gold medal in 1850, by the Society of Arts.

In 1850 Mr. C. W. Siemens became a naturalised subject of the Queen, and a year previously he had established, in conjunction with his brothers, the telegraph works of Siemens, Halske, and Co., in London, he having, notwithstanding his attention to other works, devoted much time to the study of electrical science. From these works telegraph materials have been shipped to all parts of the world, and the firm's engineers have been the pioneers of telegraphy over the entire globe. Submarine cables have also been shipped and laid in considerable numbers, and the most important of these works were the laying of the North China cable, Direct United States cable in 1874, the Platino-Brazilero cable, the French Atlantic, and the two Jay Gould cables.

For the purpose of laying Atlantic cables, Mr. Siemens designed the ss. "Faraday," a vessel remarkable in its construction, and one of the best of its class.

To record fitly what Sir William Siemens and his firm have done for the advancement of the various practical uses of electricity would involve the enumeration of an infinity of technical details, each serving to produce a complete whole. Suffice it to say that the Siemens Telegraph Works, at Charlton, near Woolwich, give at present occupation to nearly 2,000 men.

In 1851 Mr. Siemens introduced his water-meter, which has been very extensively used in this country and on the continent.

In 1853 William Siemens read a paper before the Institution of Civil Engineers on the conversion of heat into mechanical effect. This paper gained him the Telford Premium and medal of the institution. He constructed in 1866 his sample steel works at Birmingham, and in 1868 he originated the Landore Siemens Steel Works, which are among the most extensive steel works in this country.

It was in 1867 that he read before the Royal Society the classical paper of his brother Werner on the conversion of dynamical into electrical force without the aid of permanent magnetism, which important invention was likewise claimed by Sir Charles Wheatstone and Mr. Cromwell Varley.

In the science of electric lighting, Dr. Siemens was among the most successful practical workers, and a very considerable portion of the working installations of the electric light has been done by the firm of Siemens Brothers and Co. He bade fair to achieve equal distinction in the development of electricity as a power of locomotion, and the electrical transmission and conveyance of power in general. He was only the other day busily engaged in the task of constructing the first electric railway in Great Britain, recently opened at Portrush, in Ireland.

At his own place near Redhill he utilised a stream about a quarter of a mile from the house to turn a water-wheel, the power of which he transmitted by means of a wire and dynamo-electric machines, so as to use it to work chaff-cutters, washing machines, &c., and to supply light to the house. Here also he grew and ripened melons, &c., by means of electric light. He was elected a Fellow of the Royal Society in 1862, and in the years 1869 and 1870 he served on its council; member of council of the Institution of Civil

Digitized by Google

Engineers, and of the British Association; a manager and vice-president of the Royal Institution; and he was president of the Institution of Mechanical Engineers. He was also the first president of the Society of Telegraph Engineers, and in 1878 was re-elected. He was elected president of the Mechanical Section for the conferences held under the auspices of the Loan Exhibition, and gave a valuable inaugural address on "Measures." In February, 1877, after his recent visit to America, he was elected an honorary member of the American Philosophical Society, and in October of the same year was elected with Mr. Bessemer the first honorary members of the Gewerbe-Verein of Berlin. In 1871 he was brought into the Athenæum Club by the managing committee, and has since then served as a member of the same committee. He was also a member of the Philosophical and Royal Society Clubs. Dr. Siemens presented many scientific papers to various learned societies. In 1869 the degree of Doctor of Civil Law, *honoris causa*, was conferred upon him by the University of Oxford, and in 1874 he received the Royal Albert medal for his researches on heat and for his metallurgical processes. In 1875 he received the Bessemer medal of the Iron and Steel Institute. Dr. Siemens was appointed first a Commander and subsequently a Dignitario of the Brazilian Order of the Rose.

Some years ago Dr. Siemens endeavoured to obtain the sanction of Parliament to a scheme which would have gone far to render London a smokeless city. It was to construct gas furnaces in the depths of coal pits, and thence to convey the crude gas through pipes to the kitchens of our dwellings. There this gas should be burned with the coke conveyed from the pits and a perfect combustion obtained. The committee of the House of Lords, however, rejected the Bill on the sufficient ground that if the plan were of such a profitable nature as was represented it would long ago have been worked by private enterprise. Contrivances based on modifications of the same principle were exhibited some time since at the Smoke Consuming Exhibition.

On the 21st of April last Her Majesty conferred upon Dr. Siemens the honour of knighthood, and he had recently extended his researches into a new region of scientific investigation—namely, the conservation of solar energy. His last paper read to the Royal Society was on this subject, in which he detailed his own researches on the various gases which lie between the earth and the sun, and their power to absorb and retain solar heat. This brought him letters from many eminent correspondents connected with learned societies of various nations, and he was induced, by the interest it had created, to publish his paper.

The subject of this memoir was born on the 4th April, 1823, and was therefore in his sixty-first year.

---

GROUNDED.—An American contemporary is responsible for the following story:—On the electric railway lately opened by Lord Spencer, with a large number of eminent scientists, between Portrush and Bushmills, Ireland, the electricity, generated at a waterfall on the River Bush, and conveyed to the end of the line by an underground cable, is carried along through a conducting rail, which is supported on insulators at some distance above the ground. An arm with a brush or pad at the end of it stretches out from the train and keeps contact with this conductor. But on the day when the lord-lieutenant came to "inaugurate" the line it was suddenly found that there was a serious hitch. The engine declined to draw the car. The machinery was in perfect order; the connection with the conductor was all right, and yet there was no motion. Horror filled the souls of the public spirited promoters of the first electric line in the United Kingdom. It was discovered, happily before much time had been lost, that somebody had rendered progress impossible by the simple expedient of driving a piece of iron from the electric rail into the bank at the side, so that the current was being absorbed into the earth as fast as it was transmitted from the Bush. The iron being removed, the invited party made a successful trip.

## CORRESPONDENCE.

### ENDLESS CHAIN DYNAMOS.

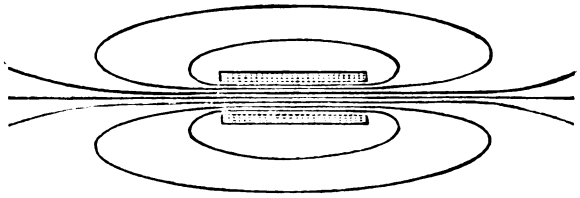
TO THE EDITOR OF THE ELECTRICIAN.

SIR: In my last letter of October 27th I did not intend to attribute to Mr. E. L. Voice the first idea of the endless chain dynamo.

I am thankful to Mr. E. L. Voice for having called my attention to the weakness of the arguments too carelessly advanced by me against the possibility of the endless chain dynamo, even with discontinuous magnetic links. Of course, the retardation of the magnetisation must be taken into account.

There is a remarkable analogy between the experiment described by Mr. E. L. Voice and that of M. de Fonvielle with the apparatus called by him *tourniquet électrique*, and described in the French periodical *L'Electricité*. In this apparatus a *continuous* soft iron disc is supported in a galvanometric coil at the place of the magnetised needle, and likewise movable. If an alternate current, like that of an induction coil, is sent through the galvanometric coil, and the disc put in motion, it will continue to rotate in the same direction of the first displacement, assuming a constant velocity depending on the intensity of the currents and the friction. This and the endless chain are both dynamos, according to the expression of Mr. A Bandsept, *sans fil de l'induit*. In the first there is discontinuity in the current, in the latter in the movable soft iron.

Retardation in magnetisation is the cause of motion in the Fonvielle *tourniquet*, and Mr. E. L. Voice attempts to explain in analogous manner the action which, according to his views, takes place in the endless chain dynamo. But there is a difference between the two instances. In the first, reversals of polarity of the coil are operating in succession on the rotating disc. Mr. E. L. Voice believes that, in the latter, analogous reversals will take place in the iron links; but it seems to me not to be the case, because in passing through a solenoid an iron core passes only through one maximum of magnetisation, which takes place a short time after crossing the central position, according to the retardation of magnetic action. The distribution of the lines of magnetic force in a solenoid, as roughly shown in the united scheme, puts the fact out of question.



The experiment described by Mr. E. L. Voice, as made by him in a factory, cannot, therefore, be explained as he did. Truly it is very puzzling. In fact, whilst the core is entering the solenoid, the co-efficient of self-induction of the latter increases, and the current, and consequently the magnetic force, must decline; and whilst the core is going out, the co-efficient of self-induction of the solenoid, the current, and the magnetic force increase. Moreover, magnetisation is not quite a reversible action; therefore the iron core after crossing the solenoid bears with it a portion of the energy of the current under form of heat. It seems, therefore, that in these circumstances the solenoid must rather act like a brake on the core than like a motor.

Could Mr. E. L. Voice remember if in his experiment some strange action had influenced the result? Dwelling now in the country I have no opportunity to repeat the experiment, which I will do after returning to Padua.

Moreover, I cannot share the opinion of Mr. E. L. Voice on the difference he states between magnets and solenoids, and I cannot understand properly his meaning when he says that "*a solenoid tends to induce, by its polarity, a pole of opposite sign, in an iron core, to that which is produced in the*

Digitized by Google

*latter by the current, thus causing two opposed induced effects.*"

The endless chain dynamo with alternate iron and non-magnetic links will certainly act as a generator, but in this case it will produce not a continuous but alternate currents. His theory is very simple. Each iron link in crossing the solenoid acts as conductor of the lines of magnetic force which go from one pole to the other of the permanent magnet. At each passage of an iron link a concentration of the lines of force in the solenoid takes place; after the passage of the iron link such an effect disappears. So if there are not "*coils cutting lines of force*," there are lines of force cutting the coil. The principle of this machine is, however, not new, as it is applied in the old machine of Page, as well as in the *coup de poign* of Breguet for firing mines; but in these machines the power of the current generated is too small in proportion to their size.—Yours, &c.,

DR. G. B. ERMACORA.

Ceresetto, Prov. di Udine (Italy), Nov. 17, 1883.

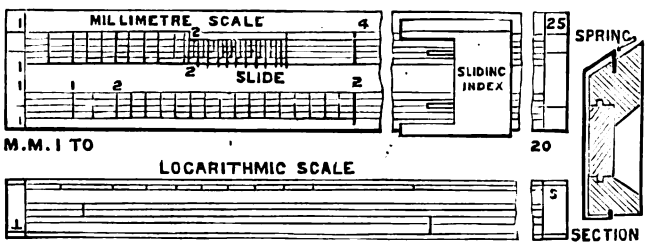
## GRAVET'S CALCULATING RULE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having been repeatedly asked by many of my friends and correspondents to give your readers a detailed description of Gravet's Calculating Rule, may I ask you, Sir, for a small space in your valuable paper?

Before proceeding further, however, let me add one or two remarks on the use and advantage of such instruments.

The slide rule is unquestionably only in its infancy; its advantages have still to be realised. It is to engineers, electricians, &c., what phonography is to reporters. It saves two-thirds of the time taken up by ordinary calculations. In choosing a rule, the first question is to obtain an accurate one; this is sometimes a very difficult thing. Now it may seem strange, but it is nevertheless a fact, that the majority of those so-called slide rules are incorrectly graduated.



Gravet's Calculating Rule.

I will not, however, speak disparagingly of any particular one, but proceed with a description of M. Gravet's.

The face of this rule is divided into four separate scales, each scale being very minutely subdivided into decimal parts.

Two are on the rule itself, two on the slide.

Calling these A B C and D, A and B will be found identical, ranging from 1 to 100.

C and D are also identical with each other, ranging from 1 to 10.

Numbers on D are therefore squared on A, and for the same reason those on D are the roots of those on A. For the purpose of marking off accurately, a "sliding index" is fitted to the rule, having two fingers, or pointers; thus you can mark off any number on C and D, whilst at the same time you mark numbers on A and B.

This "index" is a great advantage; for instance, take the following:—

$$\frac{2140 \times 3{\cdot}5 \times 2 \times 180}{12 \times 33000}.$$

This, with an ordinary slide rule, would take several operations, besides requiring a pencil to mark results. Here you place 12 on B under 2,140 on A, and move index to 3·5 on B. Under this place 33 on B, and move index to 360 on B, over which you will read 6·809, the answer on A.

On the back of the slide is a scale of tangents, a scale of series, and a scale of logarithms.

At each end of the rule is a recess, in which is placed a stroke to be also used as indices.

If we place 20 on scale T, opposite its own index, we shall have the tangent of an angle of 20 deg. opposite the 1 on line B on face of rule. Lines are also found in a similar way, as are also logarithms.

Numbers of examples might be named proving beyond doubt its superiority over other rules, but I will not further trespass on your space.

I may say that if electricians would only use this means of calculating their formula much valuable time would be saved.—Yours, &c.,

WM. FARRAR.

41, Glover-street, Leeds, Nov. 19, 1883.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice a reply to Mr. Oldham's query which puzzles me more than his initial difficulty. Till now I have always considered that "the iron bed plate" was part of the horse-shoe magnet, and that if this were omitted there would really be two independent magnets with poles above and below the windings. As I have a dynamo in hand of a similar design, I shall be glad to hear if "W. M. H." is right in his solution of Mr. Oldham's crux. If he be, am I to understand that the uncovered parts of Edison, Brush, and many other machines have some discontinuous (in a magnetic sense) arrangement studiously concealed in each? I quite agree with "W. M. H." that Mr. Oldham's speed was far too low.—Yours, &c.,

W. T. FARQUHAR.

## LOFTY POLES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to your description of a lofty pole under heading of Notes in your edition of the 10th inst., where you mention that in Coburg, Ontario, the local telephone company have a pole 68ft. high, I beg to inform you that in this district we have a dozen exceeding that length, our two highest being 105ft. and 114ft., each carrying 116 wires of phosphor bronze. The wires running right angles on one of the poles have 48in. × 40in. cross arms.—Yours, &c.,

JAMES O. FRY, District Superintendent,
The National Telephone Company (Limited),
3, Bottle-lane, Bridlesmith Gate, Nottingham Centre,
November 19, 1883.

## RECORDING TELEPHONE MESSAGES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can any of your numerous readers kindly give particulars of an apparatus invented by Mr. St. George for recording and reproducing messages forwarded per telephone, and also where and how these and his telephone apparatus may be obtained?—Yours, &c., INQUIRER.

Manchester, Nov. 19, 1883.

## ELECTRIC LAMP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Can you or any courteous correspondent oblige me with the name of the maker of D'Or's electric lamp? They were advertised by R. Heney, of the Woodlands Laboratory, Whiteley-road, Norwood, but that gentleman has disappeared without leaving any trace of his present address.—Yours, &c.,

Nov. 21, 1883. H. J. SKELTON.

## A CHLORIDE OF SILVER BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Would some of your readers kindly give me directions for the construction of a chloride of silver battery, and say if it is suitable for lighting a small, say two or three candle, Swan lamp?

What quantity would be sufficient for this, and the probable cost of material?—Yours, &c.,

Nov. 16, 1883. THETA.

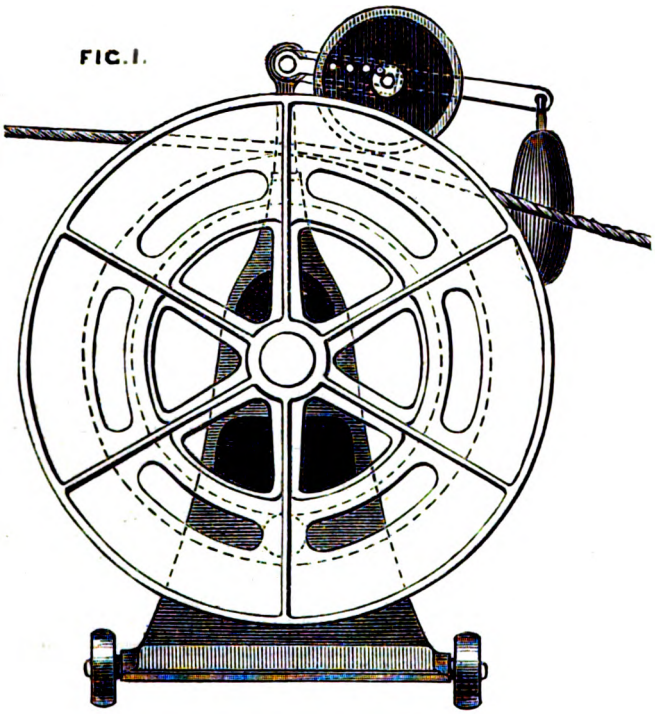
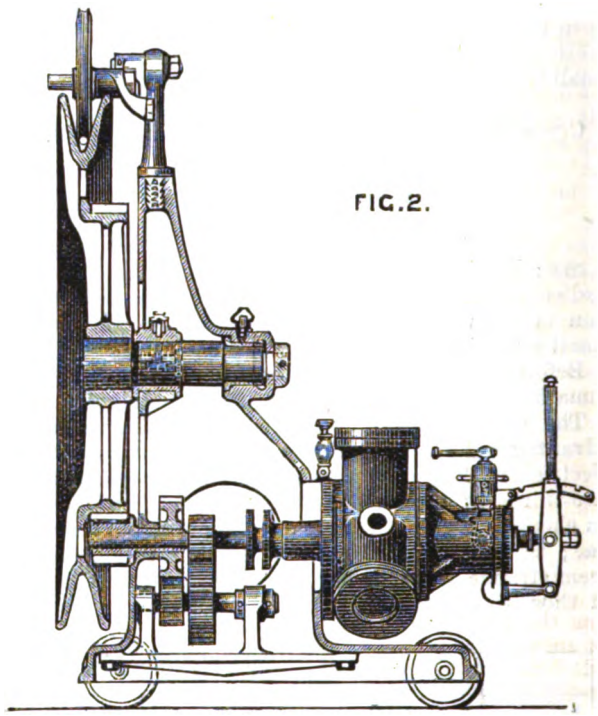
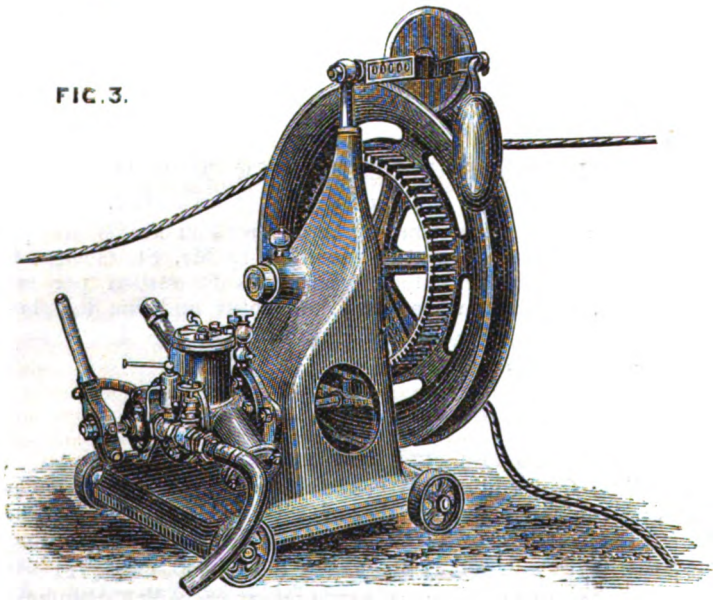
## JOHNSON AND PHILLIPS' STEAM HAULING GEAR FOR TELEGRAPH CABLES.

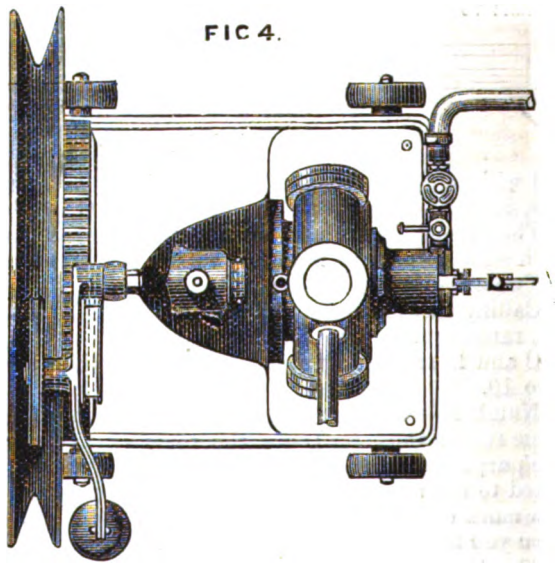
We give illustrations of a very compact machine, specially designed for use on board ships employed in cable laying and repairing operations. It will be seen on reference to the plan and elevations that the machine consists of a large V-wheel, in which the cable is placed, and into which it is tightly pressed by a jockey-wheel. It may be mentioned that this jockey-wheel is exactly half a fathom in circumference, and a revolution indicator placed on the jockey-lever, and actuated by the jockey, records the mileage of the cable which has passed over the V-wheel. The motive power is supplied by means of a three-cylinder engine and by suitable spur gearing, which is well protected by the framing; a proper motion is given to the main sheave. The engine has a reversing gear, and the steam is conveyed to it by a flexible steam hose, one end of which is joined to a connection on any convenient steam pipe which gets its supply from the main boilers of the vessel.

The machine is very easily moved about the deck, and has proved very useful on board the fleet of vessels owned by the Eastern and Eastern Extension Telegraph Companies, effecting a great saving of time and labour in the haulage of telegraph cables. We learn that Messrs. Johnson and Phillips have now several orders on hand for these machines.









Johnson and Phillips' Steam Hauling Gear for Telegraph Cables.

# A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 18).

## CHAPTER V.—TELEGRAPHS (CHEMICAL) BASED ON DYNAMIC ELECTRICITY.

Awhile forbear,
* * * * * *
Nor scorn man's efforts at a natural growth,
Which in some distant age may hope to find
Maturity, if not perfection.
*Household Words*, June 14, 1851.

### 1809—12.—SÖMMERRING'S TELEGRAPH.

Sömmerring's telegraph was based on the same principle, and was not very dissimilar in detail. There is an interesting account of this contrivance in the *Journal of the Society of Arts*,† for 1859, contributed by Dr. Hamel of St. Petersburg. According to this indefatigable writer, the war between France and Austria, in 1809, gave rise to Sömmerring's discovery. On the 9th April in that year the Austrian troops crossed the river Inn, and on the 16th occupied Munich, whence King Maximilian had fled on hearing of their approach. The Emperor Napoleon, having speedy intelligence of this move by Chappe's semaphore, hastened away with some troops, and, so rapid and unexpected were his movements, that in less than a week the Austrians were obliged to retire, and on the 25th Maximilian re-entered his capital.

This event in which Chappe's semaphore played so important a part caused much attention to be directed to the subject of telegraphy, and on the 5th July following we find the Bavarian minister, Montgelas, requesting his friend, Dr. Sömmerring, to bring the subject before the Academy of Sciences (of Munich), of which he was a distinguished member.—(Hamel, Cooke's Reprint, pp. 5—7.)

Sömmerring at once gave the matter his attention, and soon it occurred to him to try whether the visible evolution of gases from the decomposition of water by the voltaic current might not answer the purpose. He worked at this idea incessantly, and, before three days had elapsed, had constructed his first apparatus, shown in Fig. 1. He took five wires of silver, or

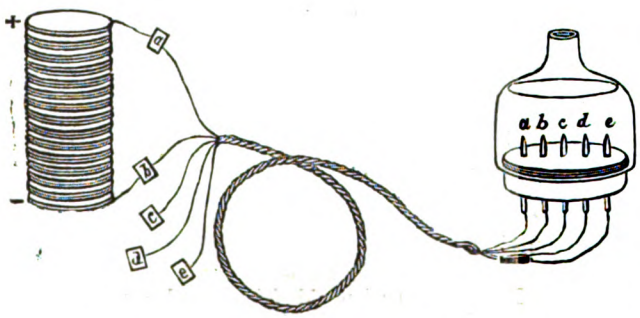

FIG. 1.—Sömmerring's Telegraph—His first Rough Apparatus.

copper, and, insulating each with a thick coating of sealing-wax, bound the whole up into a cable. These wires, at one end, terminated in five pins which penetrated a glass vessel containing acidulated water; and, at the other, were capable of being put in connection with the poles of a pile of fifteen pairs of zinc discs, and Brabant thalers, separated by felt soaked in hydro-chloric acid. By touching any two of the wires to the poles of the pile he was able to produce, at their distant ends, a disengagement of gases, and thereby indicate any of the five letters *a, b, c, d, e*. Having thus shown the feasibility of his project, he set himself to perfect his apparatus, and worked at it with such a will that by the 6th of August it was completed. He wrote in his diary on that day:—"I have tried the entirely finished apparatus which completely answers my expectations. It works quickly through wires of 362 Prussian feet." Two days later he worked it through one thousand feet, and then through two thousand feet,* the wire in each case being wound round a glass cylinder for greater compactness. (Hamel, pp. 7—8.)

As there is great diversity amongst writers on the telegraph not only as regards the date of this invention, but as to the number of wires used, and other details of its construction, we translate the following description from the author's own paper, which was read before the Munich Academy of Sciences, on the 29th August, 1809, on which occasion the telegraph was exhibited in action:—

"In the bottom of a glass reservoir of water, 170mm. long, 25mm. broad, and 65mm. high, of which C¹ in Fig. 2 is a sectional view, are thirty-five gold points, or pins, passing up through the bottom of the trough, and corresponding with the twenty-five letters of the German alphabet and the ten numerals. The thirty-five pins are each connected to as many insulated copper wires, E, E,† which, extending to the distant station, are there soldered to thirty-five brass terminals arranged on a wooden bar B¹. Through the front end of each of these terminals there is a small hole for the reception of brass pegs, one of which is attached to the wire coming from the positive pole, and the other to that from the negative pole of the voltaic column A. Each of the thirty-five terminals corresponds, through its wire, with a pin in the distant reservoir, and is lettered accordingly.

"When thus arranged, the two pegs from the pile are taken, one in each hand, and, two terminals being selected, are pushed into the holes. The communication is now established and gas is evolved at the corresponding pins in the distant reservoir, hydrogen at the pin in connection with the positive pole of the pile, and oxygen at the other. In this way every letter and numeral may be indicated at pleasure, and, if the following rules be observed, one can communicate as much as, if not more than, is possible by the common (semaphore) telegraph.

"*First Rule.*—As the hydrogen gas evolved is greater in quantity than the oxygen, therefore those letters which the former gas represents are more easily distinguished than those of the latter, and must be so noted. For example, in the words containing *ak, ad, em, ie*, we indicate the letters *A, a, e, i*, by the hydrogen; *k, d, m, e*, on the other hand, by the oxygen.‡

"*Second Rule.* To telegraph two letters of the same name, we must use a unit, unless they are separated by the syllable. For example, the word *anna* may be telegraphed without the unit, as the syllable *an* is first indicated and then *na*. The word *nanni*, on the contrary, cannot be telegraphed without the use of the unit, because *na* is first telegraphed, and then comes *nn*, which cannot be indicated in the same vessel. It would, however, be possible to telegraph even three, or more, letters at the same time by increasing the number of wires from 25 to 50, but this would very much augment the cost of construction and the care of attendance.

"*Third Rule.* To indicate the conclusion of a word, the unit 1 must be used with the last single letter, being made to follow the letter. It must also be prefixed to the letter commencing a word when that letter follows a word of *two letters* only. For example: *Sie lebt* must be represented *Si, el, le, bt*; and *Er, lebt* must be represented *Er, ll, eb, tl*. Instead of using the unit, another signal may be introduced, the cross †, to indicate the separation of syllables.

"Suppose now the decomposing table is situated in one city, and the peg arrangement in another, connected by 35 wires. Then the operator, with his voltaic column and pegs at one station, may communicate intelligence to the observer of the gas at the decomposing table of the other station.

"The metallic plates, or terminals, with which the wires are connected have conical-shaped holes in their ends; and the pegs attached to the two wires of the voltaic column are likewise of a conical shape, so that when they are put in the holes, there may be a close fit, preventing oxydation and ensuring a good contact, as it is well known that slight oxydation of the parts in contact will interrupt the communication. The peg arrangement might be so contrived as to use permanent keys, which for the 35 plates would require 70 pins. The first key might be for hydrogen A; the second key for oxygen A; the third key for hydrogen B; the fourth key for oxygen B, and so on.

"The preparation and management of the voltaic column is so well known that little need be said, except that it should be of that durability as to last more than a month. It should not be of very broad surfaces, as I have proved that six of my usual

* The author reserves all rights of translation.

† Vol. VII., pp. 595—9 and 605—10, *Historical Account of the Introduction of the Galvanic and Electro-Magnetic Telegraph into England.* Republished in pamphlet form, in Nov., 1859, by W. F. Cooke, with comments.

* On the 4th February, 1812, he worked through 4,000ft., and on the 15th March following through as much as 10,000ft.

† In September, 1811, Sömmerring reduced the number of wires to 27, of which 25 were for the letters, one for the stop, and one for the note of interrogation, or repetition (Hamel, page 19).

‡ This plan of sending the current down one wire and making it return by any other was employed by Cooke and Wheatstone in their five-needle telegraph of 1837. It proved to be a little complicated in the present instance, and Sömmerring subsequently adopted the practice of signalling only one letter at a time, the oxygen signal being neglected.

Digitized by Google

pairs (each one consisting of a Brabant dollar, felt moistened with a saturated solution of common salt, and a disc of zinc, weighing 52 grains) would evolve more gas than five pairs of the great battery of our Academy.

"As to the cost of construction, this model, which I have had the honour to exhibit to the Royal Academy, cost 30 florins. One line, consisting of 35 wires, laid in glass, or earthen, pipes, each wire insulated with silk, making each wire 22,827 Prussian feet, or a German mile, or a single wire of 788,885 feet in length, might be made for less than 2,000 florins, as appears from the cost of my short one."

On the 23rd August, 1810, Sömmerring perfected his apparatus by adding a contrivance for attracting attention at the distant station. He made the gas, rising in small bubbles from two contiguous pins in the water, collect under a sort of inverted glass spoon at the end of a long lever, which, rising, made a second bent lever in the opposite direction, on the same axle, descend and throw off a little perforated leaden ball, resting lightly on it, and which, falling on an escapement, set the clockwork of an ordinary alarum, D, in motion. This arrangement, simple as it is, gave Sömmerring much trouble. He writes in his diary, "If the principal part of the telegraph gave me no trouble, and demanded no alteration, but was ready in a few days, this secondary object, the alarum, cost me a great deal of reflection, and many

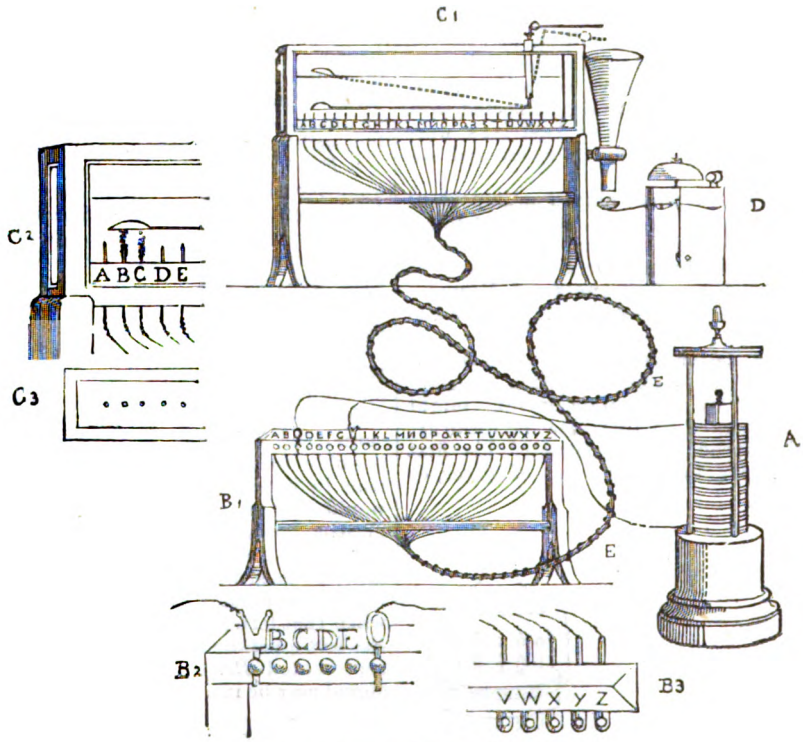

FIG. 2.—Sömmerring's Telegraph.

useless trials with wheelwork, till, at last, I hit upon this very simple arrangement." The existence of this alarum is not generally known, and, probably, because it is not represented on the two plates which accompanied the description of the telegraph in the Memoirs of the Munich Academy, which plates, as Dr. Hamel has shown, were engraved before the alarum was invented. (Hamel, pp. 13—14).

Sömmerring's wires, which were of brass, or copper, were insulated with a coating of gum-lac, then wrapped round with silk thread, and united into a cable, which was also bound with thread, and covered with gum-lac, or with a ribbon, soaked in that material. The cable was then wound on reels. In practice there was no appreciable retardation in the action of the apparatus through the greatest length of wire, the evolution of the gas appearing to begin as quickly as if the current had only to traverse two feet. The only effect of distance (*i.e.* resistance) was to reduce the quantity of the gases evolved in a given time.*

This telegraph, complex and unpractical as it was, was earnestly prosecuted by its author for several years, and received a large share of attention, princes, statesmen, and philosophers thronging to his lodgings to witness its performances. He had a complete apparatus connected up in his house, which worked through insulated wires carried round on the outside, and which he always took great delight in showing to his visitors. At the suggestion of one of the most constant and intimate of these, Baron Schilling (of whom more hereafter), Sömmerring, on the 6th June, 1811, tried the action of his telegraph when the conducting wires were cut and the ends separated by an interval of water in wooden tubs. The result was that the signals appeared just as well as if the wires had not been cut, but they ceased as soon as the water in the two tubs was connected by a wire, the current then returning by this shorter road. On the two following days he performed with his friend some other experiments, first across a canal off the river Isar, and then along the river itself, in which he showed that the water and earth might be used instead of a return wire, an experiment which was probably suggested by the similar one of Aldini, in 1802, across the harbour of Calais. (Hamel, pp. 15—17).

Besides his own apparatus, Sömmerring had prepared other models for exhibition in France, Austria, Russia, Switzerland, and England. With the latter, which, by the way, was never forwarded, "fearing difficulties at the Custom House," he sent a description in English, in which he expressed the hope that "Sir Humphrey Davy would receive it favourably, perhaps improve it, and further its application in Great Britain. (Hamel, p. 33).

The instruments designed for exhibition in Paris were entrusted to Baron Larrey (an old friend and correspondent of Sömmerring, and then Inspector-General of the Army Medical Department under the Empire), who happened to be passing through Munich on his way home from the battle fields of Aspern, Esslingen, and Deutsch Wagram. This was on the 4th November, 1809, and, immediately after Larrey's departure, Sömmerring drew up an account of his telegraph in French, under the title:—*Mémoire sur le Télégraphe*, which, on the 12th November, he forwarded to his friend at Paris, accompanied by a private note as follows:—

"I have the honour to enclose a memoir, which, with the model that you have kindly taken charge of, will, I hope, explain matters clearly and briefly. I am anxious to know what reception His Imperial Majesty will accord to my ideas. The memoir, as you will see, describes the principal results of some experiments as varied as I could make them; and I hope that they will interest many members of the Institute, for independently of the great interest that attaches to them they are not wanting in novelty." Replying on the 10th December, 1809, Larrey says:—"His Majesty, being prevented by press of business from occupying himself just now with scientific matters, has informed me that he will inspect your apparatus later on. Meanwhile I have decided to present it to the first class of the Institute, which [on the 5th December] received it with interest, and appointed a commission to report upon it."

Writing again, on the 28th December, to Baron de Kobell,

* In connection with this evolution Sömmerring noticed a curious phenomenon. Whenever the gases were evolved at two neighbouring gold points, as A, and B, the hydrogen bubbles always ascended vertically, but those of the oxygen inclined towards the hydrogen.

Digitized by Google

one of the Bavarian Secretaries of State, Larrey says :—"I have the honour to send you the little case for Doctor Sömmerring of which I have already spoken to you. Will you kindly send it on to him by the first safe means that you can find. I hope that the contents will please him.

"I shall take care to inform him of the nature of the report of the Institute upon his telegraphic machine as soon as it appears; but in this there will probably be some delay, as the academicians who have charge of the matter are greatly occupied at present on some pressing Government affairs."

The commission consisted of Biot, Carnot, Charles, and Monge, but, for some unaccountable reason (at least, Biot, in after years, could recollect none), no report was ever made, and full eighteen months later (May 12, 1811) the instruments were sent back to Munich.

Writing to Sömmerring, on April 19, 1810, Larrey says :—

"My dear and respected friend,

"Three months ago I sent to Mr. de Kobell, for transmission to you, a small case containing some remarkably diseased bones, and some brief notices upon them; your long silence makes me fear that this case has not reached you. Will you, my dear Doctor, kindly enlighten me on this point?

"I also informed you that the Institute had appointed a commission to report upon your telegraph, but certain persons, no doubt moved by jealousy, do not regard the discovery with the interest that it ought to inspire, and the report is, consequently, not yet made.

"Wishing to meet your desires, at least in part, I have inserted a notice of your instrument in the current number of the *Bulletin de la Société Médicale d'Emulation*, after having submitted it to the Society. If you have not received the Journal I will send you a copy."

* * * * *

In this paper Larrey speaks, with much detail, of the analogy which the many wires of the galvano-telegraphic cable offered to the single fibres of the nervous system, an analogy which Sömmerring himself had pointed out in his French memoir, as well as in the original account of his telegraph in the *Transactions* of the Munich Academy.* Larrey's article was republished twenty years later (in November, 1829), in his "Clinique Chirurgicale;" but, in both publications, it was placed in the midst of pathological and surgical subjects, where one would never look for an invention for telegraphic purposes.

On the 30th July, 1810, Sömmerring replied in the following curious letter :—"I have read with great pleasure, sir, your dissertation on my telegraph. Have you received my memoir, which I posted on the 12th November; and have you kindly communicated it to the Institute?

"The old conducting wires are somewhat damaged, and as it was entirely to avoid delay that I did not renew them before despatching the apparatus, I would be glad if they could be replaced by new wires of the sort used in harpsichords, covered with silk thread, as the material of which these are composed is more durable than the old copper wires. Had I imagined, sir, that you would have taken such an interest in my invention as to charge yourself with its transport to Paris, I would certainly not have omitted, beforehand, to effect the necessary changes, which, without counting the time, require only a little care. I am very much afraid that, besides the fragility of the copper wires, the rough usage to which they have been subjected in the course of experiment may have rubbed off in places the silk, and so may cause intermediate contacts of the metal, whence must result a derangement of the whole system.

"Allow me, then, to beg of you not to show the instrument to the Prince de Neufchâtel, or even to His Majesty the Emperor, until the above-mentioned repairs have been effected, either by myself, or, if its return would take too long, by some competent mechanic in Paris."

Regarding the model of the telegraph which Sömmerring delivered to Count Jeroslas Potocki, a colonel of Russian Engineers, for exhibition at Vienna and St. Petersburg, the following letter has been preserved by Sömmerring's family† :—

"Sir: I hasten to inform you that, on my return to Vienna, their Majesties, the Emperor and Empress, signified their desire to see the electric telegraph—an invention which does honour to human genius. On the first of the current month I had the pleasure to show your telegraph to their Majesties, and they were enchanted. His Majesty was so pleased that he expressed his desire to have a telegraph from Laxenburg to Vienna (a distance of about nine miles). He did not omit to ask me to whom we are indebted for so ingenious an invention. He knows you by reputation, and says that you are one of the first anatomists living. In fact, I can assure you that their Majesties, and the Archdukes, who were also present, were enchanted.

"Professor Jacquin, of Vienna, wishes to come to see me at Baaden, with the view of inspecting the telegraph.

"In fine, your invention has had the greatest success, and I do not doubt for an instant that, especially in Russia, it will be carried out on a grand scale. I shall not fail to acquaint you with the reception that it may there meet with. Meanwhile I pray you accept the assurance of the highest sentiments with which, I am, sir, your very humble and very obedient servant,

"Jeroslas Potocki.

"Baaden, near Vienna, July 5, 1811."

The apparatus which Sömmerring sent to his son, Wilhelm, at Geneva, where he was then studying, is still preserved by the family of the latter at Francfort. It was exhibited at Vienna in 1873, at London (South Kensington Museum) in 1876, and at the Paris Exhibition of 1881, at all of which places it elicited, as may be supposed, the liveliest interest.

Sömmerring, who was a distinguished anatomist and physiologist, was born at Thorn, West Prussia, on January 28, 1755, and died at Francfort on 2nd March, 1830. He was elected a member of the Munich Academy of Sciences in 1805, was made Knight of the Order of St. Anne of Russia in 1818, and, in 1819, was elected an honorary member of the Imperial Academy of Sciences of St. Petersburg. Quite recently, we believe, a monument has been erected to his memory in the city of Francfort, where he passed the last ten years of his interesting life.

Dr. Hamel, in his *Historical Account*, &c., pays a very just tribute to his worth, with which we will close this account of his telegraph :—"When one studies the life and the labours of Sömmerring, it is impossible not to feel the highest esteem for him, as a man and as a philosopher. Not vanity, not eagerness of gain, but pure love of science and the wish to be useful were the motives of his incessant activity. Nor was Sömmerring too sanguine in his expectation with regard to the application of his invention. He expressed, however, the hope that it might serve to telegraph from Munich to Augsburg, nay, from one end of the kingdom to the other, without intermediate stations" (pp. 34-5).

(TO BE CONTINUED.)

* The same analogy between the nerves of the body and the telegraphic system of the world has since been frequently noticed. See Fechner's "Lehrbuch des Galvanismus," Leipsic, 1829, p. 269; *Mechanics' Magazine*, for 1837-8, p. 262; and *Notes and Queries*, for August 27, 1870, p. 173.

† We are indebted for this and the preceding extracts to Mr. Karl Sömmerring, of Francfort, a grandson of the distinguished physicist of whom we are writing. The same gentleman has kindly lent us the original woodcuts with which our article is illustrated.

## ON SECONDARY BATTERIES AND THE ELECTRICAL STORAGE OF ENERGY.*

BY PROFESSOR OLIVER LODGE, M.A., D.SC.

*Lecture II.—Monday, May 28th*, 1883.

I must now say a few words about the methods and instruments for practically measuring the various quantities involved in the storage of energy by secondary batteries. We need current or ampere-meters, potential or volt-meters, quantity or coulomb-meters, and energy or erg-meters. The well-known dead-beat am-meters and volt-meters of Professors Ayrton and Perry are exceedingly convenient instruments, especially the former; the only objection to them is the frequent calibration they require, because their permanent magnet changes in strength. When portability is not essential I find a high-resistance galvanometer, of the form known on the Continent as the "Wiedemann," a most accurate and convenient volt-meter. The needle has a thick copper damper, which makes it almost dead-beat, and a resistance of 30,000 ohms or so has to be added to the circuit in order to bring the deflection given by one cell within moderate range. It thus taps off an absolutely infinitesimal fraction of the current.

The deflections are immediately interpreted by observing, at the same time, the reading produced by a couple of common Daniell cells in series, each of these being assumed to be 1·12 volt. There is a trifle of uncertainty about the absolute E.M.F. of even a freshly set up Daniell, and this uncertainty will continue until an authoritative standard of E.M.F. is issued by the British Association Standards Committee; but variations in E.M.F., one-thousandth part of the whole, can be readily detected; and a sensitive volt-meter is somewhat important, if fouling cells are to be detected in their early stages, and before the cell is seriously injured.

As a meter for the quantity of electricity supplied or withdrawn to the cells, I use a large copper drum, suspended in sulphate of copper on the end of a balance arm, in such a way

* Cantor Lectures. Reprinted from the *Journal of the Society of Arts*.

Digitized by Google

that it can be weighed at any moment without withdrawing it from the solution. Contact is easily made with it by means of mercury, and it is surrounded with a larger cylinder of copper, to act as the other pole. Allowing for the buoyancy of the solution in which it is weighed, every gramme increase or diminution of the drum means 1·04 ampere hour put into or taken out of the cells. Frequent weighings of the drum enable one to get a very good idea of the cells as regards charge, and they keep an accurate record of the loss, or discrepancy between the charge and discharge quantity.

A copper-drum coulomb-meter may also be made floating, so as to indicate by its height the quantity of electricity which has passed through. If such a vertical moving quantity indicator carries a sheet of sensitised paper, on which the horizontal moving spot of light from a volt-meter records a trace, the arrangement will give an indicator diagram of the charge and discharge precisely analogous to the indicator diagram for the steam engine, except that the area enclosed by the curve represents the loss of work instead of the balance of useful work. The useful work is indicated by the area between the discharge curve and the two straight lines of reference.

Many plans can be devised for combining the two traces, the quantity and the E.M.F., at right angles to one another, and the continued use of some such instrument would, I believe, assist in detecting the peculiarities of cells, and in improving their manufacture and system of treatment, almost to the same extent as the indicator throws light on the peculiarities of different steam engines. But even without such an instrument for automatically constructing the diagrams, a curve plotted in this way (with quantity for abscissa and E.M.F. for ordinate) is the readiest mode of exhibiting the results of measurement taken with ordinary meters, and making the value of the cell manifest at a glance.

A highly ingenious quantity-meter has been devised by Dr. Hopkinson, and since it indicates precisely like a gas-meter, it is easily intelligible, and may come into general use. But at the present, I believe, it only works one way, hence it is not so directly applicable to secondary batteries; it would add up both charge and discharge in one continuous record, drawing no distinction between them. The simplest power or watt-meter is the Siemens dynamometer, arranged with one series and one shunt-coil; and it indicates at any instant the power which is being supplied or withdrawn from the cells.

An erg-meter, or energy-integrator, can be made in various forms. The one I have here to show is Ayrton and Perry's modification of an eight-day clock. They substitute a fine coil of wire for the bob of the pendulum, and surround this with another larger and thick coil. A current sent in the same direction round two nearly concentric coils causes the smaller one to move to the centre of the large one. Thus, if the pendulum is oscillating, and the clock keeping good time, a current sent round the two coils will cause the clock either to gain or lose, according as the currents are opposed or agree in direction. If the two coils are both in series in the circuit, the gain or loss of the clock will indicate the coulombs passed through. But if the small fine coil is a shunt, while the other is a series, the force acting on the bob will be a function of the power, and the gain or loss of the clock will indicate the energy in some more or less arbitrary way, which can be made simple proportion by empirically adjusting the relations among the parts.

To determine the internal resistance of a battery cell, or of a whole battery, the plan is to measure its electromotive force when driving two different strengths of current, as different as possible and both known. One strength of current is most conveniently zero; the other must be measured, say, by an am-meter in the circuit. A volt-meter, such as the high resistance Wiedemann, is connected to the terminals of the battery, and read. Its indication will be a scrap higher if the current was being supplied by the cells, but lower if the current was being supplied to them. The difference of the indication of the volt-meter, when a current is passing, and when no current is passing, is proportioned to the resistance of the battery, and for a secondary battery cell in good order, the difference is surprisingly small, so much so that an ordinary volt-meter will often fail to detect it. To get the resistance of the battery in ohms, you must divide the difference in the readings of the volt-meter (interpreted into volts) by the strength of the current passing in the main circuit, reckoned in amperes. A moment's interruption is sufficient with a good dead beat volt-meter, and the current may be immediately switched on again before the disturbance in the circuit has had time to show itself, except indeed where the current is being used for lighting purposes, in which case no tricks may be played unless there are several batteries in multiple arc, and one of them can be disconnected without detriment. This, indeed, is a good plan of connecting batteries, as it allows measurements, examinations, and repairs to go on while the current is being used. The resistance of one of the small sized (half horse-power-hour) cells with nine pair of plates averages ·002 ohm. Large cells have a still lower resistance, of course, and it is to this extremely low internal resistance that the secondary battery owes much of its great practical value. The current from an ordinary Grove battery is by no means proportionate to the external resistance of the circuit unless this is high; in other words, the driving power of a cell, or the difference of potential between its terminals, falls off greatly when strong currents are demanded. But a secondary battery, from its enormous area of surface, not only gives a higher E.M.F. than a Grove ever does, but it keeps this two volts difference of potential between its terminals for pretty nearly any reasonable strength of current. Hence the current does within wide limits vary with the external resistance, and the current which such a cell will drive through a piece of thick copper wire is simply tremendous.

I must now say a few words about the uses to which secondary batteries can be applied; and, first of all, for general laboratory purposes they are invaluable. A small gas engine and shunt dynamo are necessary to charge them up occasionally, but they then retain their charge for days or weeks, according to the demand made upon them, and they are ready at any moment to produce a current, strong or weak, according to wish. They thus save a deal of trouble in setting up Grove batteries, and, moreover, the current they give is much steadier, for unless they are run to near their falling-off point, their E.M.F. continues very constant, and no compunction is felt at leaving them connected up to the circuit for a long time together—for such a time as would make Grove cells heat violently and boil over. When they are run down, a few days' charging replenishes them again.

As regards durability, the cells repay cleanliness and attention. I mount them in front of a window, on a slab of thick glass raised above the bench; one can then see all over and through them, the light being reflected from below the glass slab by an inclined bit of looking glass which can be moved about. It ought also to be possible to get on both sides of the bench, so as to be able to detect and remove any attempt at contact between the plates of a cell.

If a lump of composition tumbles out and bridges across from one plate to the next, it can be removed with a paper knife. Plenty of light, easy access, and clear vision through between the plates of each cell are highly desirable. The glass cells and the slab should also be kept clean, and free from acid splashes and spray, for all this moisture promotes leakage, and causes the cells to lose their charge more rapidly than they would by ordinary and unavoidable local action.

When cells are stowed away in dirty dark cellars, on wooden shelves, like wine bottles, the leakage must often be considerable, and the cells may get into any state of dilapidation without detection, or attempt at remedy. A light attic, or glass house, with crockery slabs at a convenient height, is a much more suitable place for secondary batteries than a wine cellar.

It is important to be able to detect an incipient flaw in a cell before it has had time to damage the cell perceptibly. A sensitive volt-meter may do this, but an ordinary one will not show any difference for a long time, and if the cell is in series with others, as soon as it begins to run down in E.M.F., the others rush it down to, and past zero, and begin to charge it up wrong way. This reversal is very bad for a cell, besides its very weakening effect upon the main current. It is very important to keep all the cells of a series as exactly alike as possible. A bad short circuit often causes a hissing noise which can be heard with a stethoscope applied to the cell, even when it is not loud enough to call your attention, as it sometimes is. But the most delicate detector of an incipient short circuit is the thermometer. All the cells heat by their proper current, but any abnormal action going on in a cell, whether it be short current or local action, or any other dissipation of energy, must result in heat, and the thermometer is the natural detector of this. Any cell warmer than the others should be examined, and set right, or else replaced.

The lugs and contacts should be wiped clean occasionally from the acid spray which collects on them, and they may also be recoated with paraffin and shellac. This acid spray is thrown up by the bubbles of gas which rise when the cell is getting full. The hydrogen bubbles throw up largish globules, which bound two or three inches into the air, and fall all over the slab and terminals; but when hydrogen comes off freely, the cell is commonly quite full. The oxygen which comes off slightly during the greater part of the charging, throws up much more minute globules, which float about as an acid spray, very irritating to the nostrils and very provocative of leakage. The spray may be greatly diminished by a layer of oil spread over the surface, in which the bubbles collect and break in a different way, and it also checks evaporation; but the oil introduces difficulties of its

Digitized by Google

own when the plates have to be lifted out of the cell, though indeed it may be first flooded off. The contacts of the positive plates are very apt to be corroded by the spray and creeping film, together with the per-oxidising action of the current crawling up wet lugs, and they require occasional attention. Unless absolute uniformity of contact is secured, some of the plates will take nearly all the current, and get peroxidised to pieces, while the others are nearly idle.

I use pans of very dilute ammonia, or perforated boxes of carbonate, to neutralise the acid spray. The atmospere is then much improved, and instead of acid films, white crusts of ammonia sulphate collect, which are less harmful, and may be cleared off. Another precaution is always to keep the cells filled with acid above the level of the plates, so that they are completely immersed, else the part above the liquid will be exposed to the influence of non-concentrated acid, from the evaporation of the water out of the acid film covering it. It is important to remember that all these exposed layers of acid are likely to become pretty concentrated, and hence that they may be expected to corrode more rapidly than the mass of the solution.

Another advisable precaution is to stir or agitate the liquid occasionally, more particularly during charging. The bubbles of gas, fortunately, do this to some extent, if the cells are well filled up electrically; but if no such agitation is excited, the acid at the bottom of the cell is apt to become very much more concentrated than that at the top. Not that gravity is able to pull down strong acid out of once thoroughly mixed dilute acid. Gravity cannot undo diffusion like this. But it is the acid freshly formed during re-charging, by decomposition of the sulphate of lead on both plates—it is this acid which falls to the bottom and accumulates there, frequently corroding the bottoms of the plates. One great advantage of the present cells over the old flannel-swathed Faure, is that they permit free circulation of the liquid. To make the cells answer various laboratory requirements, I have a sort of resistance-box, made with uncovered spirals of German silver wire, in a stoneware water trough, so that the wires do not melt, and I can then throw in any resistance from a quarter ohm upwards, otherwise the current would be frequently too strong. For working a Serrin lamp no extra resistance is necessary, and from eighteen to twenty-two cells work it admirably. Even when one drives the lamp direct from the dynamo the battery is still connected as a shunt circuit to act as a regulator and steady the current. Moreover, it has the great advantage of preventing the engine from racing away when one puts out the lamp. A well-governed engine of course ought not to do this in any case, but I have not found a gas-engine behave well when work is thrown on and off it in such an irregular and fitful manner as a lamp is commonly used in a lecture. It is much better for it to be pumping into the cells whenever the lamp is put out. Moreover, one can get a far more powerful current through the lamp in this way than from a small dynamo direct. Another advantage of having the battery connected is that it will not permit the locking of the carbons, and thus the short circuiting of the field magnets of the shunt dynamo, which is a not infrequent occurrence when a shunt dynamo alone is used to feed an arc lamp.

If, however, only a regulator is wanted, and not a store of energy, a set of zinc and lead plates can be easily arranged, which will do all that is wanted in the way of regulation; and as the lead gets gradually more and more "formed," the battery will gradually acquire more and more actual storage capacity. The cells were very useful once when the gas-engine was being repaired. I took the dynamo over to a neighbouring steam-engine, and laid its comparatively full current with spans of common wire to the battery. From the battery thus charged, the powerful occasional currents needed for some magnetic researches then going on were readily obtained. To bring such currents from the distant dynamo would have necessitated the use of very thick and expensive cable, and would, in fact, have seriously damaged its armature.

The battery thus acted as a transmuter of weak currents into strong ones, and this illustrates on a small scale one of its very important future functions, viz., a receiver of energy transmitted from a distance, as Sir William Thomson has pointed out. Currents generated at a distant station, to be conveyed to a distance, ought not to be strong; they ought to be feeble currents at a high potential. They can be received by a great number of batteries in series, and the batteries so charged can be used for any local purposes, and made to give any reasonable desired current by altering their connections. Moreover, they can be coupled up to a number of independent circuits, so that irregularities in one shall not interfere with the others. The great advantage of a set of batteries as a receiver, over a set of dynamos in series, is that the latter would need such a high internal resistance to give the necessary back E.M.F., whereas a battery, even of small cells, can give 1,000 volts E.M.F., with an internal resistance of only 2 ohms. Hence the waste in heating the receiver is next to nothing. There is another kind of waste, no doubt, for the work got out of a battery can never be anything like that put in. The E.M.F. of charge is about 2·3 or even 2·4 volts, while that of discharge is scarcely above 2; besides this, there is a slight loss or discrepancy between the quantity supplied and that afterwards withdrawn. Notwithstanding this waste, they must come into use when made in a satisfactory and quite dependable manner, for their great convenience and steadiness. And when the power at the distant station is water or wind-power, as I doubt not it often will be, waste becomes of secondary importance, and a convenient method of storing is the first consideration.

So plainly is high E.M.F. pointed at as the requisite for the economical transmission of energy, that I cannot help thinking that, in some cases, a use will be found for electrostatic machines as generators instead of dynamos. Not exactly a Holtz machine—which has a high internal resistance, and must dissipate energy, from its use of non-conductors and sparking intervals—but some gigantic form of Thomson's replenisher with metallic contacts. A large machine is needed to give a current of one ampere, but not outrageously large, and a clear separation of the parts by a millimetre will enable 4,000 volts E.M.F. to be obtained. No great horse-power is here represented, but it would be transmitted by a well insulated wire with very small loss.

In using a waterfall running continuously to light a town for, say, eight hours, batteries are evidently desirable. Three sets might be used, each charging for eight hours—one or other of them always charging, and two of them discharging during the eight hours the light is required. Or two sets would be sufficient if the water-power itself could be used for lighting direct. But the use of three sets of batteries would enable a reasonably distant waterfall to be used, and would, for the eight hours the light is needed, give an actually greater horse-power than the fall itself possesses.

For locomotion in cases where the current cannot easily be supplied to the moving carriage by metallic conduction, as in tramcars on common streets, batteries carried by the tramcar afford an obvious, and, moreover, an economical form of motive power. It is sincerely to be hoped that electric tramcars may speedily come to perfection, and that the excessive wear and tear of horseflesh in this monotonous and severe labour may be checked.

[A number of motors were exhibited, some lent by the Electrical Power Storage Company, and some by Professors Ayrton and Perry. A De Meritens motor, driven by eighteen storage cells, was used to drive a small Siemens dynamo by a strap, the current from this being used to drive another motor, which worked a lathe, or was used to light four small Swan lamps. A Pilsen arc lamp was shown, working very steadily with the current from the battery, and a number of Swan lamps were also excited, so as to show how entirely any one was unaffected by the turning out of the others, a battery behaving in this respect like a very good compound wound dynamo. Diagrams of the mode of connecting up cells and dynamos for transmission of power and curves representing the charge and discharge of cells, as tested by Dr. Hopkinson and Messrs. Ayrton and Perry, were also exhibited, but it is thought unnecessary to reproduce them here.]

For driving boats electrically, secondary batteries are obviously necessary, because the laying on of a current by a wire is not only inconvenient but impossible. The storage cells will act as ballast, and can be charged while the boat is moored. For swift short voyages, and for pleasure vessels, nothing better than electrical propulsion is likely to be devised. For long voyages and big ships, the weight of secondary batteries would need all the floating power the ship possesses, and perhaps more. The energy consumed in propelling the present Atlantic liners is something almost incredible.

When motors are driven by secondary batteries with very short connecting wire, the question arises, is high E.M.F. still desirable, as it is when transmission across great distances is concerned, or may powerful currents be now used with advantage? The answer is that, neglecting the resistance of battery and connecting wires, there is neither gain nor loss in using powerful currents, provided the dynamo is properly wound, and has brushes that will not burn up.

But if we do not neglect the resistance of the batteries—a thing we have no right whatever to do—the answer is that high E.M.F. is of very great advantage. A large number of cells in series, driving a high E.M.F. dynamo at its highest possible speed, and with as small a current as is needed for the power, is by far the most economical arrangement. Now, a screw for a ship has always needed a high speed for economy, and in the old days gearing used to be employed between the steam engine and

Digitized by Google

the screw because no high-speed engine was sufficiently economical. I understand that slow engines are still the best, but the disadvantages of gearing are so great that high-speed direct-acting engines are always used. But a high speed is absolutely essential to economy in an electric motor, and no screw, as ordinarily made, would work at such a speed; consequently, there is a temptation to use gearing the other way, and to gear down the dynamo to suit the screw. I hope the attempt will be resisted, and high-speed screws made of small size, smooth surfaces, and low pitch, so that the electric motor axle may be coupled direct to the screw shaft. The direct rotatory action of a dynamo used as a motor, as opposed to the oscillating action of a steam-engine, is a great simplifier of mechanism, and will be found extremely convenient.

For all kinds of short transit locomotion, electric power will, probably, prove to be the most suitable, and the improvement in the atmosphere of the Underground Railway which would result from the adoption of such a means of propulsion, would be far more remarkable than anything which ventilators, whether ornamental or the contrary, are able to effect. In fact, there can be little doubt that the practical development of electrical appliances in the near future will be something extraordinary, and the consequence of this, and of the extensive use of gaseous fuel, will be, I most sincerely hope, and not unreasonably believe, not only the abatement, but the compulsory abolition, of smoke and all other artificial pollution of the atmosphere, and such an improvement in the air of towns as will change them from stifling purgatories into wholesome and refreshing centres of life and work.

## PARLIAMENTARY NOTICES FOR NEXT SESSION.

In the ensuing Session of Parliament an application will be made for an Act to transfer to and vest in the Edison and Swan United Electric Light Company (Limited) the powers of the Edison and the Swan Companies under the provisional orders relating to the St. James's and St. Martin's, Strand, Hanover-square, South Kensington, and Victoria districts. The Act will ask for authority to exclude or provide for the exclusion from the areas of supply included in the orders, or some of them, "any district or districts, or part or parts of any district or streets, in which any other company, person or local authority may by provisional order, license, or Act of Parliament, to be granted or passed during the ensuing Session of Parliament, be empowered to supply electricity, or any other district or districts, or part of any district or street which may be excluded by the Bill, and in the event of any such exclusion to provide that all the duties, obligations, and liabilities of the Edison Company and the Swan Company respectively, or either of them, in, or in connection with, such districts, or parts thereof, shall cease and determine." Power will also be asked to alter or repeal "all or some of the provisions of the before-mentioned Orders and Confirmation Acts, or some of them, and of the Telegraph Construction and Maintenance Company (Limited) Act, 1883, or any other Acts relating to that Company, so far as may be necessary or expedient for the purposes of the Bill, and to incorporate with the Bill all or some of the provisions of the Electric Lighting Act, 1882, with such modifications and exceptions as may be provided in the Bill." Authority will also be asked to dissolve, if thought fit, and to re-incorporate the United Company, conferring upon it the powers referred to, and if thought fit to amalgamate the Edison and the Swan Companies.

The United Telephone Company (Limited) notify their intention of applying for an Act authorising the Company, or a new company to be incorporated, or their agents, to break up streets, erect posts on, and to lay or carry wires for telephonic communication under or over any land, house, street, or other place within the City of London and the limits of the metropolis as defined by the Metropolis Management Act 1855, subject to conditions, restrictions, and regulations prescribed from time to time by the Board of Trade or other public authority, "or otherwise as shall be provided by the intended Act." Powers will be asked to "authorise the company or the new company, for the purposes of the intended Act, to acquire, sell, manufacture under, or otherwise use, any patents and licenses for the transmission of telephonic communication, and also to grant licenses to manufacture under or use any such patents either within or without the aforesaid intended district;" and "to authorise the company or the new company for the purposes of the intended Act to make, levy, and recover rates, rents, and charges, and to grant exemptions from the payment of such rates, rents, and charges."

The India Rubber, Gutta Percha, and Telegraph Works Company (Limited) intend to apply for an Act to explain and remove doubts as to the effect of the Memorandum and Articles of Association of the company, and to declare that the Memorandum of Association "shall be deemed to confer upon the company powers for the following purposes:—

"The construction, laying down, maintenance, purchasing, hiring, letting, selling, working, and use of telegraph cables, or of works, materials, gear, and apparatus, and all other things required for or in connection with the production, transmission, use, and application of electric, magnetic, galvanic, hydraulic, or other forces and matters incidental thereto.

"The purchase, manufacture, and sale of torpedoes and torpedo boats and all matters and things connected therewith.

"The employment, application, and use of india rubber, gutta percha, gums, wire, hemp, skins, elastic, and other substances for any purpose for which they may wholly or in part be adapted, and generally the manufacture of and dealing in all articles and things made wholly or in part of the said materials and substances, or any of them, or any other material, substance, article, or thing, of what nature or kind soever, which the company may deem it desirable to manufacture or deal with in connection with their business; and the carrying on of any work or business connected with or incident thereto, and the use or application of any such materials or substances.

"The holding of property and the establishment of works, and generally the carrying on of business both in and out of the United Kingdom.

"The holding of shares, stock, and debentures in other companies."

Authority will be asked conferring on the company all powers which may be necessary or expedient for effecting these objects, and to vary and extinguish all rights which would in any way interfere with the objects of the Bill.

Notification is given of the intention of applying for leave to bring in a Bill to incorporate a company with powers to construct the "Mid-London Electric Railway." The proposed railways are four in number, and will commence opposite No. 518, Oxford-street, proceed along New Oxford-street, Holborn, to Cheapside (opposite Honey-lane), and thence to "the centre of Cornhill, at or near the south-west corner of the Royal Exchange."

Application is intended to be made for an Act incorporating a company, and conferring on it powers to make the "London Central Electric Railway." The railways will commence (No. 1) by a junction with the line authorised by the Charing-cross and Waterloo Electric Railway Act, 1882, about 58 yards from its commencement, and terminate in the parish of St. Giles, about 20 yards east of Dudley-street; railway No. 2 will start from or near the north-east corner of Regent-circus and Piccadilly, and end at the termination of railway No. 1; railway No. 3 will begin at the termination of railway No. 2, and terminate about 40 yards west of the north-west corner of Newgate; and railway No. 4 will begin at the end of railway No. 3, and terminate about 30 yards east of the north-west corner of Panyer-alley (opposite the General Post Office). Parliament will also be asked to sanction the making of certain agreements between the Company and the Charing-cross and Waterloo Electric Railway Company as to the construction, working, &c., of the projected railway.

## THE EASTERN EXTENSION, AUSTRALASIA, & CHINA TELEGRAPH COMPANY (LIMITED).

The twentieth ordinary general meeting of this Company was held on the 14th inst., at the City Terminus Hotel, Cannon-street, under the presidency of John Ponder, Esq., M.P.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting, and the minutes of the nineteenth general meeting, held last April, which were confirmed by the present meeting, and signed by the chairman. The report of the directors was taken as read.

The CHAIRMAN: Before making a few general remarks, I will give you some of the figures as showing the result of our working during the last six months (to June 30th). The gross receipts for the half year have been £213,729, as against £207,119 for the corresponding period of 1882, showing an increase of £6,610. The working expenses have been £62,778, as against £50,355 in the corresponding period, being an increase of £12,423. This increase of course requires some explanation. The difference is principally accounted for by the following items:—Ships' expenses (which includes the cost of the "Sherard Osborn" for the whole six months, rendering assistance to the contractors in the China waters in laying shore ends and the river portion of the cable between Hong Kong, Foochow, and Shanghai) show an increase of £6,200. If our ship had not done this work the expense incurred in sending a ship from this country by the Telegraph Construction Company would have been something like £20,000 additional upon the cost of the cable. Station expenses, which include the expenses of the new China station for January, although the cables were not opened till towards the end of the half year, exhibit an increase of £4,337. In short, we were paying for establishments from which we were not deriving any corresponding advantages. The expense of the new issue of capital also absorbed over £1,000. The net revenue for the half year was £107,356, against £113,393 for the corresponding period of 1882, showing a decrease of

Digitized by Google

£6,037, which is explained by the abnormal expenditure to which I have already referred. The dividend and bonus on the old and new shares to the 30th of June have been distributed, amounting to £75,000. Of this £59,925 was paid on the old capital, and £15,075 on the new issue. The balance carried over to the next account is £32,356, against £23,468 in the corresponding half year. As to the new issue of capital, the calls shown in the balance-sheet to be outstanding at the close of the half year have since been paid. From the 1st of July last the old and the new shares have ranked *pari passu*. Although the new China cables were laid in the early part of the year, as stated at the last meeting, the opening of the lines, owing to many difficulties raised by the Chinese authorities, was delayed for several months, during which time more than the normal expenses under ordinary circumstances were necessarily incurred without any corresponding return. At the last meeting when I had the honour of addressing you I gave you a very full description of our negotiations with the Chinese, and our reasons for having our head-quarters at Shanghai, and the opening of the connection with China has been upon the whole a very successful movement. The Chinese, I may mention, are a very far-seeing people. They are not particularly anxious to have the European element much amongst them, but we find when we come into direct negotiation with them they are amenable to reason, and the result has been that, on our steadily maintaining our views of what we believe will benefit them as well as us, and keeping those views constantly before them, we have been, I may say, successful in establishing what must eventually be productive of very great benefit to this country. China is beginning to adopt European notions of trade, and the people are seeing the value of mechanical inventions. I believe before very long we shall see railways rapidly extending in China. I know from communications I have had with the Chinese that their minds are entirely in that direction now, and we know that the result of railways in any country, especially in such a country as China, where labour is so cheap, and the soil so productive, must lead eventually to very large and increased traffic with China. That increased traffic must find its way to this country, principally through telegraphic communication, because, as I have often said at these meetings, the telegraph has become one of the most important agents of commerce. We hear a great deal every day now about what the Suez Canal has done for the commercial and shipping interests of this country. Why, you might shut up the Suez Canal to-morrow without commerce feeling any great inconvenience; but if you were to shut up the submarine telegraph system which now permeates the whole world, you would so convulse commerce that it would be almost impossible to bring it back to its usual channels; certainly it would take a considerable time before you could do so. The mail steamers receive enormous subsidies for conveying letters, which, when they arrive, are old documents. Letters now simply register a transaction which has been created and carried through by submarine telegraphs. I think it well that those gentlemen who are interested in trade, and who have taken an active part in submarine telegraphy from its inception, should know that this system is now, and will become more so in its commercial and political effects, the ruler and controller of the progress of the world. Gentlemen, during the six months we have had rather an important break of our cable—namely, between Madras and Penang. It was unfortunately during the monsoon, and a cable breaking during the monsoon was almost considered an impossibility to repair in former times. I am glad, however, to say that the cable was repaired duing the monsoon, and that fact must give us additional confidence in submarine telegraphy as a property. As you are aware, we have two cables connecting Java and Darwin. One of them broke. In repairing the one we broke the other, and it so happened that we picked up the end of the old and the end of the new, and spliced them together. By this means we were able to maintain communication until the weather improved sufficiently to enable us to repair one cable thoroughly. Our new cable—the last cable—is now in perfect working order; and as to the old cable, the ship is on the spot, and we expect to have a report every hour that it has been repaired. The Australian people, appreciating the immense importance and value of submarine telegraphy, are now about to hold a conference to consider how far it is possible to induce us by guarantees or subsidies of some sort to reduce our rates. Whenever we can see that commerce is likely to be promoted and our receipts increased by lowering the tariff, we are prepared to cheapen the rates. We have, however, intimated to the colonies that the risk must be borne by them, and that if they secure to us something like what we are earning at the present moment, giving us all the benefit of the natural increase which springs from telegraphy, we shall be quite prepared to make such arrangements as will secure them a considerable reduction in their tariff. I mention these facts because I have already stated what an important link there is existing between telegraphy and commerce, and we ought not, therefore, to stand in the way of its progress. We are not going to take up the position assumed by the Suez Canal authorities and say we are to have 50 per cent. before our customers get any benefit from it. We think the interests of the Company and its customers must go hand in hand. Those who provide the traffic are entitled to some consideration, and those who give the benefit of submarine telegraphy are also entitled to consideration for the boon thus conferred. That is the policy we are pursuing, and I hope it will meet with the approval of our shareholders, and the general approval of the mercantile community to whom we look for support. As in commerce so in politics and in war. We are now likely to carry to a successful issue our negotiations with the French Government to connect their possesions in China with our system. The negotiations are still going on, and looking at the telegraph system as an international one, we are always ready to help any nationality, because we believe there is no greater instrument that can be used in the cause of peace than telegraphy, and we are always ready whenever any country wants our assistance to help by connecting their territories with our system. I therefore hope that we shall be able shortly to announce that we have completed an agreement with the French Government for connecting Saigon with Tonquin. I mentioned the last time I had the honour of addressing you that we were replacing a great deal of our cable that had been more or less injured by the teredo. We nave already replaced portions of the teredo infested sections with brass-ribboned cable, which we have reason to believe has been entirely successful in keeping out our little enemy; consequently we are gradually and steadily replacing the old cable with new. As to the dreadful earthquake which took place at Java, and which destroyed a very great extent of that country, we, ourselves, suffered very little; I believe £100 or £150 would cover the whole of the loss we sustained. But the Dutch Government suffered considerably, and we have to-day completed a contract with them for laying some £9,000 worth of cable to replace the Sunda Straits line, which was destroyed by the earthquake. I daresay you have seen from the papers that, looking at the small loss we sustained from this disaster, we acted promptly and sent through the Minister £250 on the part of this Company to go towards relieving the distress. We find that a little prompt action in that way is never lost on people who are in the main our customers [loud cheers]. With these remarks I beg to move "That the report and accounts of the directors now submitted be received and adopted." [Cheers].

The Marquis of TWEEDDALE: I beg to second the motion.

The CHAIRMAN: If any gentleman has any remark to make before I put the resolution I shall be very glad to answer him.

Mr. G. BARHAM: I think I should like to ask one or two questions. In Clause 6 you say, "After some protracted negotiations, &c.," but you do not say what those negotiations are likely to bring us—what we may anticipate from them. You have explained two or three items of the increased expenditure, but there is one item that you have not explained. The general expenses in London have gone up something like 20 per cent., roughly, and that means rather a large expenditure. Working expenses at the stations have increased some £4,000, you say. That is so, and is accounted for, I presume, by your getting ready for the Chinese traffic; but what that traffic will do for us I should like to hear. There is another point that you omitted to refer to, namely, that the directors' remuneration has been increased something like 25 per cent. The auditors' remuneration has been increased by something like cent. per cent. I think these matters require some explanation. Roughly the working of the half year fully seems to be this:—Compared with the previous half year you have half a million more money. With that at 6 per cent. you required some £15,000. You have got extra expenses, £12,000, making altogether an increased expenditure on the half year of £27,000, whereas you have only an extra receipt of £6,000. I want your very serious consideration to that. You know the unfortunate position that most telegraph shareholders are in in the majority of cases. This Company has just managed to keep the shares at some slight premium, but in the majority of cases they are at a discount. I do hope that the Board will not indulge in extravagant expenses, but that they will so manage as to keep the Company in—I was going to say its present happy position, but it is not so very happy after all with only five or six per cent.; but at all events I hope they will so manage that we may look for the present dividend to be maintained. I am glad to hear your remarks about reducing the rates. It is very rarely that I have occasion to send a telegram abroad, so you see I am not speaking in an interested way when I say that we are right in taking into consideration at the first opportunity the advisibility of reducing the tariffs. I am pleased to hear your remarks on this point, because you know that when a tariff is kept at too high a rate, it induces competition. Therefore, it is very much better to reduce the charges before you get a competition than to wait until you have one. I shall be very glad, and I am sure the proprietors generally will be very glad to hear what we may expect from the China traffic.

The CHAIRMAN: I will answer the personal question first—that is, as to the increase in the directors' fees. I am afraid that Mr. Barham was not present at the last meeting, or he would have found that I was perfectly straightforward with the shareholders. I stated that for a time the directors had reduced their fees by £1,000, but that the time had come when they thought they were entitled to return to the old remuneration. I mentioned also that we had effected for a time a very considerable saving in not appointing another managing director on the death of Colonel Glover. The most strict person that we have had probably at these meetings—at all events the one who has watched with the greatest care and the greatest interest the expenditure, namely, Mr. Newton—that gentleman not only approved of those proceedings on our part, but he thought the time had come when the directors were fairly entitled to return to their old rate of remuneration. If you would take the trouble to refer to my speech at that time, you would find that I stated the whole case to the shareholders, and they were unanimous in approving of our going back to the old sum. The auditors' remuneration was also increased. There was also some increase given to the staff; in fact, there was a vote carried outside the Board altogether to give certain increases. In regard to the increase generally in the last half year, we have been paying money on capital which has not come fully into play; consequently, we are in the position of having met, and something more than met, all our increased outlay, and still we are paying the same dividend that we paid you before, and we carry a larger sum forward than we have done on previous occasions. I am always glad to have fair criticism—and I do not say that Mr. Barham's criticism is in the least degree unfair—but if he asks me to tell him what is to be the increase on the telegraphic system with China, I can only reply that we have to deal with an enormous trading population, and if there is the same progress, or even a proportion of the progress in telegraphy as there is in the advance of commerce in other nations, I think we may look for a very large increase in the course of time. We cannot, however, jump into it in a day. Mr. Barham asked me to explain something of the negotiations that are going on at the present time. I do not think that you, the shareholders, generally would ask me to tell you about a half finished bargain. I do not think it would be right to those who are negotiating with us or fair to ourselves to lay our hands bare until we know what the result will be. You must trust to us; but we are watching your interests very carefully, and if we make a bad bargain we shall have to come before you to justify it, or to hear that we are not the parties to make a bargain. I only make the statement that we are in negotiation for connecting Saigon with Tonquin for the French Government. What the result of the negotiations will be I am not prepared to say. They may not be completed.

Mr. BARHAM: I am not asking you for that. You say in Clause 6, "After some protracted negotiations, &c." I am asking for information about that point, not as to the negotiations that are pending.

The CHAIRMAN: That applies to China, and I think in the remarks I made in my opening speech about China I have given you a very large

Digitized by Google

amount of information. I have said that by downright dogged perseverance, and by dealing with the Chinese as we should wish to be dealt by ourselves, we have succeeded in establishing friendly relations with China. We have got our cable landed at Woosung and at Hong Kong, and at Foochow I expect we shall be able to complete our connections very shortly. Therefore, we have done pretty much all that I had ever shadowed forth that we were likely to do in China. As to what the return may be we have not yet had sufficient experience, but China is slowly but gradually developing, and probably the development may be most rapid, and everything in connection with commerce in China will add something to our telegraph traffic. I think with these remarks that I have nothing further to say in answer to Mr. Barham.

Mr. NEWTON: I should just like to mention that I was present at the last meeting, and I cordially approved of the increased remuneration being paid to the directors. I think if you will look about telegraph properties generally you will find that, with the exception of the Submarine Company, this Company stands highest, and I think the management of this Company is beyond praise. The negotiations that have been referred to are of a very delicate nature, and we must trust the directors to do what they can. In dealing with a barbarous or semi-barbarous country there are various ways of going to work which in the long run come to £ s. d. We must trust the directors, therefore, and not look to a small sum here or there, having regard to our enormous revenue. As to the directors' fees, here we have a company paying 6½ per cent. to its ordinary shareholders, and carrying a large amount to reserve fund. Looking at the reserve fund, there is a very great revenue there, and that reserve fund is rendering your dividend permanent, and probably 6½ per cent. is not the maximum, and you may see it much larger. I quite agree with paying directors well if they are doing well for the shareholders. I should like to ask you one question. I did not look over the traffic returns, for I am sure they are satisfactory, but I should like to know whether the complex state of affairs in China and France will improve our revenue? I think but for that disturbance our property would have been higher, and I think the feeling in the minds of the shareholders is one of fear. I think it will benefit rather than prejudice the revenue of the Company, even if the worst comes to the worst there. On the question of reducing your tariff I believe there is a great source of revenue from such a proceeding as that, as it will enable merchants to send their letters by telegraph. Within the last six months I have seen a letter that would have been sent *verbatim* to one of the places we telegraph to if the charges had been somewhat less, but with 4s., 5s., or 6s. a word to pay people hesitate, and send their messages in cypher. If a little more liberal terms were offered for letters not sent in cypher, I believe merchants would avoid sending their letters by mail, and would send them instead by telegraph.

The CHAIRMAN: I will answer Mr. Newton's question as far as I can. I think Mr. Newton has done what I quite expected he would do to-day. He has justified the directors when they are right, and he takes every opportunity—and very properly so—of blaming them when he thinks they are wrong. That is the way we desire to be judged, and I am always desirous, when I hear of men of Mr. Newton's position, anxious to see everything go on right, support the directors on an occasion of this kind. As regards the war in China, I do not think it is going to do us much harm. It may interrupt our commercial relations a little, but the enterprise of the Press in the present day is so great that during the Cape war I have known sometimes our penny papers pay the South African Company £500 for a message from the Cape to this country. Depend upon it they will have the same thing in China, such is the competition and such is the desire to have the greatest amount of information to place before the public. I may also refer to the Egyptian difficulty. When the war was going on last year the Eastern Telegraph Company were at very great expense, and kept their ship at Alexandria, and did all they could to keep up telegraphic communication with Alexandria. The consequence was that they were thanked all round; but the public received the news at the expense of the Press, who showed a wonderful amount of enterprise and paid handsomely and liberally. There was no limit to the amount of money they were prepared to spend if they could only get information that was worth placing before the public. Therefore I do not expect in the first instance that any great loss will occur to the Company if there should be war in China. But when the war is over I expect an enormous increase in the traffic, because we know that progress very often comes from that cause. I believe this may happen with China, as with other countries.

Having put the motion in the usual way he declared it carried unanimously, and the business of the meeting concluded.

Mr. L. MARCUS: I think before we separate, after the very satisfactory report that the directors have placed before us, we should thank them, and I beg to propose that a vote of thanks be given to them on this occasion.

The motion having been seconded and carried,

The CHAIRMAN said: Gentlemen, as usual, I have great pleasure in thanking you for this renewed expression of your confidence, and I trust that we shall always be in a position to deserve it.

The proceedings then closed.

## TRAFFIC RECEIPTS FOR OCTOBER, 1883.

Preliminary Advertisement.—In the High Court of Justice, Chancery Division. Re the Duplex Electric Light, Power, and Storage Company (Limited).—Plant, Machinery, Stock, Office and Show Room Furniture, Fittings, and other effects.

MR. FRANK LEWIS (of Messrs. Frank Lewis and Co.), the person appointed by the Judge to whose Court the above cause is attached, will SELL by AUCTION, on the Premises, No. 9, SOHO-SQUARE, and 12, RATHBONE-PLACE, OXFORD-STREET, early in December, the whole of the PLANT, Machinery, and Stock, comprising Voss and other electrical machines, Baudet's, Siemens', and Patrick's dynamos, air pumps, resistance coils, galvanometers, electric bells and gongs, App's and other induction coils, arc and duplex lamps, large quantity of brass electroliers of various patterns, porcelain shades and arc lamp globes, Morse instruments, electrical toys, large quantity of Bunsen's Smee's, Leclanché, and other cells, of all sizes, vacuum tubes, 1,000 flat porous pots, 7,000 glass bulbs, for incandescent lamps, 20 gross stoppered bottles, 3 cwt. glass tubing, 1 cwt. ebonite slips, 500 Siemens soft core carbons, brass work, including terminals, connectors, lamp top holders, &c., about 3 tons curled zincs and zinc cylinders for Bunsen cells, about 2 tons of lead sheets, 3 cwt. paraffin wax, quantity of bichromate, copperas, peroxide of lead, acids, and chemicals, about 3 miles No. 16 G.P. covered core, about 1¼ ton wire double cotton covered, 8 20-gallon stone-ware acid pans, lead-lined cases, quantity of p.p. teak and birch for battery boxes, a nearly new 20 horse-power engine by Robey, fitted for electric lighting purposes, an 8 horse-power portable ditto, by Marshall, of Gainsborough, a back geared screw cutting lathe, 6¼in. centre, 7 other lathes, shaping machine, drilling machine, large grindstone, shafting and pulleys, hurricane forge, anvils, 20 vices, tools, 5 cwt. Pooley's weighing machine, carpenters' benches, &c., also the office, show room, and other furniture and fittings, consisting of mahogany writing tables, chairs, glazed show cases, marble top tables, partitioning and numerous other items. May be viewed two days before sale, and catalogues had on the premises, of Messrs. Munns and Longden, Solicitors, 8, Old Jewry, E.C.; of S. Lovelock, Esq., the Official Liquidator, 19, Coleman-street, E.C.; and of Messrs. Frank Lewis and Co., Auctioneers, &c., 95, Gresham-street, E.C.

CHANGE of ADDRESS.—The BARNSLEY CARBON COMPANY have REMOVED their LONDON OFFICE to 20, DARTMOUTH-STREET, WESTMINSTER, S.W., where a stock of Carbon Rods, Consolidated Battery Plates, Leclanché and Manganese Batteries will be kept for immediate delivery. Makers of Hedges' Cut-outs and Fusible Safety Plugs. Works, Barnsley.

Digitized by Google

## NOTES.

PROFESSOR TYNDALL.—It is stated that Professor Tyndall has resigned his position as adviser to the Irish Lights Commission.

RESIGNATION.—Mr. Keatinge Pollock has ceased to be manager of the Metropolitan Brush Electric Light and Power Company.

AURORA BOREALIS.—A brilliant aurora was observed in Paris about five p.m. on Monday last. It appeared on the western horizon, and lasted several minutes.

NEW CABLE.—News from the Hague says that the Great Northern Telegraph Company will ask for a concession from Holland for a second cable from Harwich to a point on the Dutch coast.

EDISON SYSTEM IN THE BANQUE DE FRANCE.—The installation of 60 Edison lamps in the Banque de France, Paris, has been increased to 250 lights, which will light the entire printing department of the bank.

ELECTRIC LIGHTING IN ST. LOUIS, U.S.A.—Several electric light companies have been asked to tender for the lighting of the new Custom House in St. Louis. Power will be supplied, but the companies are to find everything else.

THE EDISON SYSTEM IN NEW YORK.—This plant is now in its fifteenth month of continuous running. The company are at present lighting 508 houses, wired for 12,732 lamps, of which 10,164 are actually attached to the conductors, available at will.

APPOINTMENT.—Mr. T. H. Seymour Hawker, electrician to the Birmingham and Warwickshire Electric Light Company, has, on that company's amalgamation with the Hammond Company, joined the latter, taking the management of the Birmingham branch.

PATENT EXAMINERS.—The Civil Service Commissioners are about to hold an examination for six additional assistant-examiners to the staff of the Patent Office, at a salary commencing at £250, and rising by £37 10s. triennially to a maximum of £400 per annum.

CUTTING WOOD.—Herr Günther, of Zerbst, has, according to *Dingler's Journal*, invented a wood cutting machine, in which a number of platinum wires are united in a frame, and heated by a current from a battery. The wires are utilised to cut logs into boards, as is at present done with saws.

FALMOUTH-BILBAO CABLE INTERRUPTED.—The Direct Spanish Telegraph Company notify the interruption of their Falmouth-Bilbao cable. Telegrams for Bilbao, Madrid, and other places in Spain can, during the interruption, be forwarded by the route of the Eastern Telegraph Company.

ELECTRIC LIGHTING ON WAR SHIPS.—The French man-of-war, "Richelieu," has been lighted by means of incandescent lamps. The installation was carried out by the well-known firm of Sautter, Lemonnier, and Co., of Paris, and comprises 250 lamps, with the requisite machine, fittings, &c.

ANOTHER ELECTRIC RAILWAY.—It is proposed to construct an electric railway between Bar Harbour and Eagle Lake, Mount Desert, U.S.A. The distance is three miles, and is at present covered by conveyances drawn by horses. The line will be known as the Mount Desert Railway, and it is stated that it will be begun very shortly.

A HINT FOR ENGLISH THEATRES.—An amusing adaptation of the Edison light has been made at the Bijou Theatre, Boston, U.S.A., in the last act of "Virginia." The two red horns on the devil contain 16-candle lamps, which, being connected to the Edison system in the theatre, are lighted when the devil disappears upward, producing a striking effect. The entire theatre is also lighted by Edison lamps.

ACCIDENTS FROM LIGHTNING AT CYPRUS.—On 31st October, during a violent thunderstorm, a native who was riding near the village of Archa was struck by lightning, and he and the mare he was riding were both killed. On the same day a woman and an ox were struck dead by lightning at Sotira; and near the same village, on the following morning, a man and a mare he had been riding were found dead, having been struck down by the electric fluid.—*Cyprus Herald.*

THUNDERSTORM AT BOURNEMOUTH.—A very severe thunderstorm passed over Bournemouth on Sunday night, the lightning striking the chimneys of Little Forest House on the East Cliff. The house was not occupied at the time, and the fire was therefore not immediately discovered. The building was burnt to the ground. Some valuable pictures were saved by the fire brigade, but the remainder of the property, worth several thousand pounds, was destroyed.

AN AURORA IN THE SANDWICH ISLES.—A magnificent aurora is stated to have been visible in the Sandwich Islands in September last. A letter received by M. L'Abbé Bund states that the horizon seemed on fire, and that the aurora appeared now in the west and now in the south. It is said to have remained visible until sunrise. Auroras are rare in these latitudes, and the appearance of the one above mentioned is ascribed to the extreme dryness that has prevailed during the year.

ELECTRIC LIGHTING FOR THEATRES.—M. Wybauw, a Belgian engineer, has sent in a report to the Burgomaster of Brussels on the lighting of theatres by electric lights. He details what has been done in this way at Vienna, Brünn, Prague, Berlin, Dresden, Munich, and Frankfort, and the conclusion at which he arrives is that the Monnaie Theatre, in Brussels, ought to be lighted in this way also. He says: "It is objected that this means of lighting is dear; in my opinion it costs what it is worth."

EARTH CURRENTS.—In a recent communication to the Academy of Sciences, M. Blavier states that the direction and strength of earth currents depend on the difference of potential between the two points where the telegraph wire is in contact with the earth, and not upon the length of the circuit. Between Paris and Nancy there are two circuits of very different natures; they have both given the same result, however. M. Blavier has also ascertained that subterranean lines are not more affected by earth currents than ærial lines.

THE BELGIAN SOCIETY OF ELECTRICIANS.—The first meeting of this society took place early in this month. It was proposed by the president for the time being that they should form a branch of the International Society just established in Paris. This was, however, strenuously opposed by several gentlemen, who were in favour of founding an entirely independent society. In the end it was resolved to ascertain how far the International Society would entertain the proposal that the Belgian Society should form a branch of the former.

SHIP LIGHTING.—The ss. "Orlando," of the Wilson Line, of Hull, has been lighted throughout with Swan incandescent lamps. The current is supplied by an alternate current machine excited by a small dynamo of Opperman Brothers' make. The "Orlando" has left Hull with mai s and passengers for Gothenburg. We understand that incandescent lamps are used for both masthead and side lights, and that Captain Watson, the master of the steamer,

Digitized by Google

expressed himself well pleased with the new mode of lighting.

Underground Telegraphy.—A successful trial of Brooks's Underground Conduit Company's system was lately made in Philadelphia. This company has now in operation a substerranean pipe containing 33 wires from Third and Chesnut Streets to the depot of the Pennsylvania Railroad Company at Kensington, a distance of two and a half miles. The cable is laid 18 inches underground. The Western Union Telegraph Company has 10 of its New York wires in the pipe to Kensington, which are being used for transaction of ordinary business.

Hoisting by Electricity.—The Northern Railway Company of France have utilised electricity for hoisting and stowing bags of sugar at one of their quays. A trolley with four wheels is fitted with two small Siemens dynamos, one to actuate the trolley and the other for hoisting work. The current is supplied by a Gramme machine placed in a workshop 300 metres away. It is said that the work of hoisting and stowing the sugar can be far more quickly accomplished by this new method than when manual labour was employed as in the past.

Electric Lighting for Lighthouses.—Not long ago we stated that a series of experiments were about to be undertaken at the South Foreland in order to decide the respective merits of gas, electricity, and oil as lighthouse illuminants. We learn that for this purpose three towers have been erected, where the necessary apparatus will be fixed. It is, we believe, not intended to entrust to a committee the duty of arriving at a decision on the subject, but it is expected that representatives of public bodies and of foreign Governments will be invited to witness the experiments.

Earthquake Phenomena.—Dr. Hector, F.R.S., stated at a meeting of the Wellington (New Zealand) Philosophical Society, that his two self-registering barometers had shown a remarkable up and down vibration on the revolving drum upon which the record is marked on dates corresponding with those of the Sunda earthquake, and a severe earthquake twenty-six hours afterwards, which was felt along the northern coast of Australia. This agitation was quite distinct from those caused by ordinary atmospheric influences. He attributed the curious tidal disturbances which occurred on the New Zealand coast in August to those earthquakes.

International Society of Electricians.—The first meeting of this society was held on the 15th instant. M. Cochery, Minister of Posts and Telegraphs, presided. It was announced that on that date no less than 1,100 members had joined. The rules of the society were approved, but the election of officers was postponed to the next meeting, as it was found necessary to considerably add to the number originally proposed. It was decided that the executive committee shall be composed of 50 French members, and one or two from each foreign nationality. There will also be six vice-presidents, six secretaries, and two treasurers. The date of the next meeting has been fixed for the 13th of December, at 8:30 p.m.

Curious Advertisements.—We have been favoured by Mr. A. J. Frost with copies of the two following advertisements. The first is from *The Times* of Thursday, Nov. 22, 1849, and reads as follows:—"Wishaw's General Telegraph Offices, 9, John-street, Adelphi, London. A choice of electric telegraphs, at £40 per mile. Apply to H. Corbett, Esq., Sec." The second is from *The Times* of Sept. 26 or 27, 1850, and runs thus:—"Submarine Telegraph. Gentlemen connected with the original Dover projection (or any gentleman interested in the matter) may hear of two distinct inventions for conveying the wire through the most interrupted route and roughest sea. Address to the inventor, Mr. Peter T. Turner, Margate."

Electric Lighting in Hull.—It is more than probable that the Hull Town Council will continue Messrs. Siemens Brothers' contract for lighting certain parts of the town for another six and possibly twelve months. The present contract expires in a few weeks. Should the contract be renewed it will be upon the understanding that several alterations are made in the positions and candle-power of the lamps used. The borough surveyor handed in a report to the last council meeting, in which he specified the alterations he thought necessary, and Messrs. Siemens will be asked to carry them out. The general opinion of the council seemed to be in favour of the electric light, though there were a few who complained of unsteadiness, flickering, and so on.

Catalogue.—We have received a neatly got up catalogue and price list from the Anglo-American Brush Electric Light Corporation. The engravings of machines and lamps, of which there are a good number, are well executed and capitally printed, so that the details of the subject are nicely brought out. In addition to the well known type of dynamo used for arc lighting, the catalogue contains illustrations of the more recently built machine for incandescent lighting, which has been named the "Victoria." We find also illustrations of incandescent lamps, switches, regulators, cut-outs, head-light lamps, search lights, and other details. At the end are given the prices of the various machines, lamps, and fittings, and altogether this catalogue and price list is a useful publication. We notice that the general management of the company now devolves upon Mr. Frank Wynne.

The Telephone in Scotland.—The Glasgow branch of the National Telephone Company have just completed for Messrs. W. Denny and Brothers, of Dumbarton, a very extensive system of telephone service in their yards at Dumbarton. The Messrs. Denny are one of the largest shipbuilding firms on the Clyde, and, besides their extensive yards, have engine works, forge, and foundry. It will therefore be seen that their various departments extend over a very large area, and the advantage of having them all connected together by telephone is very great. The system is arranged in this way:—A room has been set aside as a switch room, in which the switch board is placed, with an operator in attendance, similar to any ordinary telephone exchange. Wires from all the different departments, private houses, &c. —twenty-two in number—run into this exchange, and can be connected together. A wire also runs from the exchange to a signal cabin, where stands a tall signal post, which can be worked from the cabin. By this means any foreman who is wanted can be signalled for. The system is, we believe, likely to be extended to other departments.

Electric Lighting at Brighton.—At a meeting of the Brighton Town Council, on Thursday, Nov. 22nd, Mr. Councillor Carpenter moved a resolution rescinding two previous decisions of the council—one a resolution authorising application to Parliament to obtain compulsory powers to purchase certain properties for central electric lighting stations, and the second directing application to be made to the Local Government Board for sanction to borrow £60,000 for the purpose of carrying out the Brighton electric lighting order, 1883. Mr. Carpenter contended that the electric light wherever introduced had proved a failure, and thought it was unadvisable to proceed to introduce it to Brighton. Mr. Councillor Sturt-Urston seconded. A long discussion fol-

Digitized by Google

lowed, during which Mr. Alderman Reeves moved an amendment, instructing the gas committee to defer all action in reference to the order until May next year, at which time they were to report again. This was eventually adopted, Mr. Carpenter withdrawing his resolution. The provisional order expires in 1885.

Electrolysis of Bismuth Solutions.—Messrs. N. W. Thomas and E. F. Smith have described in the *Chemical News* some experiments in the electrolysis of bismuth solutions. The authors employ solutions of the sulphate or citrate of bismuth, the latter either alkaline or acid. In some experiments the solutions to be examined were put in a platinum crucible, which was surrounded by a coil of wire in connection with the negative pole of a battery, the positive electrode being suspended in the solution. On the passage of the current metallic bismuth is deposited on the interior of the crucible, and can be washed, dried, and weighed. In other experiments the platinum crucible is suspended from a wire connected with the negative pole in the solution in a beaker, the positive electrode being likewise in the solution. In this case the bismuth is deposited on the outside of the crucible. The authors find that the method works well and accurately. The time required to deposit the bismuth varies according to the strength of the solution, and is not shortened by application of heat.—*Journal* of the Chemical Society, for November.

An Electric Watch.—Last week we mentioned that, according to a cable message, a young Jew of St. Petersburg, named Schisgal, had invented a watch that goes by electricity. Herr Chowlson, Professor of Physics at the University of St. Petersburg, has written an article on the subject in the *Nowosti*, in which he says:—"In its remarkable simplicity this invention can only be compared with the Jablochkoff system of electric lighting. The watches are without any springs, and consist solely of two wheels. Besides being true, they have the advantage of the second hand moving in single momentary leaps, as is usually the case only in very costly watches, and which is of the utmost utility for astronomical observations. These watches can also set in motion a certain number of watches of the same construction, so that they all keep exact time. The invention has convinced me that watches can be used for the purpose of telegraphy." After naming several other advantages, Professor Chowlson describes the invention as a wonder which will cause an entire revolution in the manufacture of watches. Herr Schisgal is the son of a Jewish watchmaker in Berditschew.—*Electrical World.*

Bearings and Friction.—A bright and well-known mechanic insists that on his swiftest moving journals he obtains the best results with cast iron on cast iron, and he is willing also to depend on an emery-ground fit. Another, perhaps equally authoritative, says that for exceptionally high speeds, as 4,000 revolutions per minute, cast iron and cast iron are inadmissible, but he employs untempered steel and hard Babbitt metal well hammered into the box and then bored out. He tried hardened steel boxes and soft steel spindle for that speed, and found that the boxes cut so rapidly as soon to destroy the spindle as well as the boxes. For heavy weights and large journals there appears to be nothing that gives better satisfaction than good Babbitt boxes hammered solidly. Cast-iron boxes with wrought-iron or steel spindles have done well where the weight and speed are not excessive. All soft metal bearings, as Babbitt or composition, ought to be protected from the grinding influences of dust, but cast iron, if kept well oiled, soon forms a glaze that is almost indestructible. In all cases the journal should give space enough for a film of oil, especially for high speeds, under which it may become heated and slightly expanded. Many journals and boxes are injured by binding, the consequence of a too finical fit.—*Scientific American.*

Government Telegraphs in America.—*The Operator* is not in favour of Government telegraphs or Government anything else, as will be seen by the following extract from an article in its last issue. Our contemporary says:—"All we wish to add is that we have tried Government railroads on the Continent of Europe, and Government telegraphs in England, and that we did not like either service at all. If 'Virginian' [a correspondent who writes in favour of Government telegraphs] continues to feel a strong interest in Government control of the telegraphs, we recommend him to read the bitter things that leading London newspapers say of the English service, and also to study John Stuart Mill's powerful utterances on the limits of the province of Government." All we wish to add to the above is that our telegraph service is about the best in the world—the old world, we mean. Everything is so well done in the New World that it would be vain to hope to approach it. We are not sure that we should not like a Government railway system for England as well as a postal and telegraph system. There are a good many anomalies in the matter of rates that want looking into. Then, again, our telephone system is not a very brilliant example of private enterprise—at all events in London. We are not sure that we should not rather welcome a Government Telephone Department. However, our friends in the New World are welcome to their dislike of governments, *chacun à son gout;* and if they prefer private enterprise and occasional chaos to system and order, why that is no business of ours.

The Telephone and Newspaper Enterprise.—The enterprising proprietors of several local papers published in Lancashire have had the whole of their various offices connected by telephone. Thus the *Bolton Evening News and Bolton Weekly Journal, Farnworth Journal and Observer, Pendlebury and Swinton Journal, Eccles and Patricroft Journal, Leigh Journal and Times,* and *Tyldesley Weekly Journal,* are all within speaking distance of one another, per telephone. From both the counting-house and editorial departments at Bolton communication is established with the offices at Farnworth, Pendlebury, Eccles, Leigh, and Tyldesley, the entire circuit having a total length of twenty-three miles. The advantage of such a system of intercommunication is obvious, and no doubt Messrs. Tillotson and Co., the proprietors of the foregoing journals, will find that as "time is money," time saved is money made. At all events they deserve to do so. The wires have been put up, and the instruments and apparatus fixed in the various offices and departments by the Lancashire and Cheshire Telephonic Exchange Company. It will be interesting to add that telephonic communication for business and general purposes is making considerable progress in Lancashire, the company having opened exchanges at Bolton, Manchester, Liverpool, Wigan, Chorley, Darwen, Blackburn, Preston, Rochdale, Southport, Blackpool, Chester, Bangor, and many other towns in Lancashire, Cheshire, and North Wales. In nearly all of the towns in question they have also private lines. Altogether the company have nearly 3,000 miles of wire and about 5,000 instruments—the Blake transmitter and the Bell telephone. The head office is at 38, Faulkner-street, Manchester, and the secretary and general manager is Mr. Kenneth MacIver.

Influence of Pressure on a Metal and Liquid in Contact.—MM. E. Bichat and R. Blondiot have made

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.
Digitized by Google

experiments on the influence of pressure on the electrical difference between a liquid and a metal in contact, the result of which they have communicated to the *Journal de Physique*. In a tube of Cailletet's apparatus they solder two platinum electrodes. One of these is electrolytically coated with copper, so far as that portion of it within the tube is concerned. The tube having been filled with sulphate of copper, it is put in its place in the ordinary way. The two electrodes are connected with the terminals of a capillary electrometer, in such a way that the copper-covered electrode is in connection with the top of the electrometer. This instrument will then show the E.M.F. of the battery (copper, sulphate of copper, platinum) at the pressure of the atmosphere. If pressure be applied, it will be found that the mercury of the electrometer re-enters, so as to mark a difference of E.M.F. of about one thousandth of a volt at 100 atmospheres. So long as the pressure is maintained, the couple retains its new E.M.F. If the pressure be suddenly removed, the mercury in the electrometer immediately returns to its first position. The effect noticed cannot be attributed to an elevation of temperature due to compression. They have, in fact, directly ascertained that rise of temperature would produce an inverse action to that observed. Further, the fact that the electromotive force remains persistently modified during the whole of the time that pressure is maintained, is sufficient to show that it has nothing to do with caloric action. Repeating the above experiment with a platinum-silver couple in a solution of nitrate of silver, they observed a variation of the same kind, but feebler, amounting to about the half of a thousandth of a volt at 100 atmospheres. If, instead of the above couple, they used either (1) platinum-copper in water or (2) platinum-silver in water, no appreciable change occurred either when pressure was applied or when it was maintained at 100 atmospheres ; which, they think, certainly points to the fact that the actions on the two electrodes being equal in their absolute value compensate each other. In fine, they state that they have placed beyond doubt the influence of pressure on the electrical difference between a liquid and a metal.

The Late Sir William Siemens.—The funeral of Sir William Siemens took place on Monday last. If anything had been wanting to show the esteem and regard in which he was held by his fellow-workers, both practical and scientific, it would have been supplied in Westminster Abbey by the well-known faces that met the eye wherever one turned. The Royal Society, the Society of Telegraph Engineers, the Institution of Civil Engineers, the Society of Arts, the Iron and Steel Institute, the British Association, the Royal Institution, the Institution of Mechanical Engineers, and other scientific bodies, all sent representatives to do honour to one who had done so much for the various branches of science they represent. The Prince of Wales was represented, and Count Münster, the German Ambassador, was also present. Application had been made to the Dean of Westminster for leave to bury Sir William in the Abbey itself, but the Dean was constrained, owing to the extremely limited space now available for burials, to answer in the negative. Permission was, however, readily granted for the first portion of the burial service to be conducted in the Abbey, the remainder being concluded in Kensal Green Cemetery, where it was decided to inter the body. The pall-bearers were chosen from the following bodies, viz. :—Royal Society, Professor Huxley; Society of Arts, Sir Frederick Bramwell ; Institution of Civil Engineers, Mr. Brunlees; Institution of Mechanical Engineers, Mr. Percy Westmacott; British Association, Sir William Thomson; Royal Institution, Professor Tyndall; Society of Telegraph Engineers, Mr. Willoughby Smith; Iron and Steel Institute, Sir James Ramsden. It is impossible for us to give a tithe of the names of those who were present in this brief note, and we can only repeat what we have said above, that they represented every branch of science and practice, from Professor Tyndall and Sir William Thomson to the workmen in the factory of the firm of which Sir William was such a brilliant representative. Very many of the relatives of the deceased were also to be seen, including Dr. and Mrs. Werner Siemens, Mrs. Carl Siemens, Mr. and Mrs. Alexander Siemens, and others. The coffin was covered with wreaths and flowers, some of which were sent from the Woolwich works, the Westminster offices, and the Berlin house. The inscription on the coffin plate was simply: " C. William Siemens, died 19th November, 1883, aged 60 years." The number of carriages which followed to Kensal Green was very large. We may mention that Messrs. Siemens' works in Berlin and Charlottenburg were closed on the day of the funeral. One of the last marks of appreciation of Sir William Siemens' services to the iron and steel industry was conferred upon him by the Council of the Institution of Civil Engineers, shortly after the accident which caused his death, in the shape of the Howard Prize. It does not often fall to the lot of men to rise to such a height amongst their fellows as did this once poor but clever German lad, nor is the death of an individual often so widely felt. If anything can help to mitigate the grief of his family, it will be the widespread and heartfelt sympathy that has been shown for their loss.

A National Exhibition at Budapest.—It is intended to hold a general national exhibition at Budapest in 1885 There will be an international section in this exhibition,which will be devoted to motors, working machines, and tools for artisans, as well as agricultural machines of the latest and most improved constructions, and also important patented inventions and improvements. The exhibition is being got up by the Government,who invite the participation of foreign makers and inventors. For the benefit of those of our readers who may care to exhibit we make the following extracts from the general regulations, a copy of which has been sent us :—The exhibition will be opened at Budapest on the 1st of May, 1885, and closed on the 15th of October following. The special exhibition comprises the following first and secondary classes :—First Class A: Motors (engines), work machines and tools for artisans and the smaller trades. I. Secondary Class : Engines to be set in motion—By gas, water, steam, hot air, electricity, carbonic gas, carbolhydrogen, &c. II. Secondary Class: Various machines and tools for working wood, metals, textile fabrics, &c. All inventions are accepted, if secured by the patent still in force of any country at the time of exhibition. Not only perfected objects but also their models will be admitted. No prizes will be awarded by a jury. During the permanence of the exhibition, however, a technical scientific commission of experts will be constituted, based on regulations hereafter to be issued, which commission will examine the articles exhibited, and will issue certificates in the name of the general commission. The special committee will take the necessary steps to procure favourable reductions of tariffs and fares on all lines throughout the Austro-Hungarian territory, as well on the carriage of all objects to the exhibition, and, if necessary, on their return journey. The importation of objects free of duty has been provided for. Should an exhibitor claim the privilege of having his patent-rights protected, he must send in a petition, enclosing vouchers, properly filled out, to the Royal

Digitized by Google

Hungarian Ministry of Agriculture, Industry, and Commerce, before sending in his objects. Applications must be written on special forms, which will be forwarded to applicants in duplicate, free of charge, by the special committee, which forms must be filled out properly, written clearly, and filed at the office of the general commission, at latest by the last day of February, 1884. The said general commission will be answerable for a prompt and quick despatch of all applications, and will pay every attention to the correspondence with exhibitors. Exhibitors of inventions and improvements must annex to their application an authenticated duplicate of their patent. Exhibitors intending to exhibit in several "First Classes" must file two vouchers for each and every class. With regard to objects announced for exhibition, the special committee has to decide whether they will be accepted or not, as far as the object of the special exhibition is concerned; but as a superior court the general commission has the right of final decision. Neither the commission nor the committee are obliged to give reasons for refusal. To facilitate the examination of the applications, every application must be accompanied by a drawing with detailed explanation, and, with regard to machines, it must be stated how much water, steam, gas, and how much driving power is required. In case of acceptance of objects for exhibition, the exhibitor will receive a certificate of admittance within 30 days after filing his application. The propelling power (water, steam, gas) and the transmission from the main shaft for putting machines in motion, will be given free of cost, and be at the disposition of the exhibitor; yet the expenses of mounting and keeping in proper order of all the gear for transmission from the main shaft must be borne by the exhibitor. The time of motion during the exhibition will be fixed by the special committee at the proper time. All steam engines will be examined before they are put in motion by the special committee, at the expense of the exhibitor. Further particulars can be had of the General Commission of the General National Exhibition of 1885, Budapest, Hungary.

Ventilating by Means of Electricity.—In the *Jährbuch für das Berg- und Huttenwesen in Sachsen*, 1883, p. 30, Mr. B. R. Förster gives an account of the application of electricity to the ventilation of colliery workings, which is translated in "Abstracts from Foreign Transactions," &c., published by the Institution of Civil Engineers, and from which we make the following extracts:—The apparatus, which has been executed by Messrs. Siemens and Halske, consists of a small steam engine at the surface, driving a primary dynamo, the current generated being transmitted by a copper wire to the secondary dynamo, which is coupled to the ventilator underground. The steam engine is of the rotatory piston kind (Dolgoruki's system). The available work measured by a friction brake is 2·56 h.-p. This engine is somewhat larger than is actually required for the work, as, according to Siemens and Halske, one of the same size in their works, working at $5\frac{1}{4}$ atmospheres boiler, or $4\frac{1}{2}$ atmospheres piston-pressure, realised 9·36 h.-p. In the present instance the effective boiler-pressure is only $3\frac{1}{2}$ atmospheres. The actual steam consumption cannot be very accurately determined, owing to the difficulty of taking indicator-diagrams upon engines of this class. Assuming, however, that a well-constructed engine of such small power should realise 50 per cent., the gross h.-p. for the above duty will be 5·12 h.-p. The dynamos are of the well-known Siemens construction, and both are of the same size, No. D 8 of the makers' list. The armature of the primary machine is attached to the crank-shaft of the steam-engine, and revolves at the same speed (eight hundred revolutions per minute). The conductor joining the two machines is carried 112 metres (367ft.) above ground, 261 metres down the shaft, and then 407 metres through the workings. It consists of a copper wire, 7·25 millimetres (0·28in.) diameter, carefully supported upon stoneware insulators, placed at intervals in the shaft and levels. The conductor for the return current is formed by an old steel wire pit-rope, of 30 millimetres (1·18in.) diameter, for a distance of 377 metres, while for the remaining distance a copper wire similar to the main conductor is used. The wire-rope was originally laid along the ground, where, however, it soon became very rusty from the damp, so that it has since been suspended from hooks driven at intervals into the roofs and sides of the level. The secondary dynamo drives the ventilator by a strap, the shaft of the former making one hundred and twenty-four revolutions to one hundred of the latter. The ventilator is a simple centrifugal fan, by G. Schiele and Co., size No. 8, 1 metre in diameter, with a discharge-pipe of 0·196 square metre surface. The delivery at five hundred revolutions is stated to be 180 cubic metres of air at 20 millimetres pressure, requiring 1·66 h.-p. to drive it. The fan is placed in the sixth main level, north from the Carola Pit, and is arranged to supply air through pipes of 300 millimetres (1ft.) diameter to four workings lying in different directions. As previously stated, the available power of the engine, measured by the friction-brake when making eight hundred revolutions per minute, was 2·56 h.-p.; that of the secondary dynamo-machine, similarly measured when at the surface, with a circuit of only 50 metres, was 1·4 h.-p., corresponding to a useful effect of 54·3 per cent. The resistances of the current, and losses by friction of the rotatory part, and in the conversion of electric into mechanical energy for these conditions, are about 45·7 per cent. of the total energy of the motor. The ventilator underground makes three hundred and sixty-one revolutions per eight hundred of the surface-engines, at which speed the volume of air moved at 198 cubic metres per minute. As regards the cost of working, the wear of the electric engines is very small, being principally confined to the brushes of the commutator, which probably will not exceed £5 yearly. Materials for lubrication and cleaning cost about £12 10s. yearly, or $11\frac{1}{2}$d. per day. No special engine-drivers are required, as the total daily work about them can be done in a quarter of an hour. The cost of steam, according to the conditions prevailing at the mine, is £9 6s. 9d. per h.-p. per annum, or, for 5·12 h.-p., £29 16s., equal to 2s. $7\frac{1}{2}$d. per day of twenty-four hours, or per 285·120 cubic metres of air delivered. Interest and depreciation on the cost of the plant amount to a further 2s. 8d. per day, making a total of 6s. 3d. per day, or per cubic metre 0·00015d. (about 3d. per 1,000,000 cubic feet). The above figures, however, refer only to the theoretica quantity of air delivered at atmospheric pressure, while under the actual condition of work, with the fan blowing into several lines of pipe going in different directions, the delivery is very much smaller. Thus it was found that when blowing through five lines of pipes, with a total length of 200 metres, the total volume was only 31 cubic metres, which was further diminished to a total of 12·81 cubic metres when the length of pipes was increased to 567 metres. The cost per cubic metre would therefore be, in the first case, $\frac{198}{31} = 6{\cdot}4$ times, and in the second $\frac{198}{12{\cdot}8} = 14{\cdot}6$ times as much as that given above. The use of such very long lines of pipes must, however, be regarded as exceptional.

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 31.)

**Electrolytic Balance of Chemical Corrosion.**—Any mixed electrolyte with a current passing through it and setting free one only of its constituents at a corrodible cathode, and the current then gradually increased until a second cation constituent just begins to be deposited, constitutes an example of "electrolytic balance." Such a case is that of an acidified solution of cupric sulphate, with copper electrodes, with the current increased until metal begins to be deposited; or that of the ordinary cyanide of silver plating solution containing much free potassic cyanide with electrodes of silver, similarly treated.

Such a silver solution, suffering electrolysis at its "balance point," forms an excellent illustration of the compensation and balance of a number of molecular forces, the alteration of any one of which disturbs the remaining ones. Even a change of temperature may be included in this statement. It is a case of balance of powers in which the state of equipoise depends upon the united and simultaneous action of at least seven or eight different influences, viz., ordinary chemical corrosion, strength of current, nature of cathode, size of cathode, temperature, proportions of water, of argento-potassic cyanide, free potassic cyanide, and of the soluble salts, &c., present in the form of impurities. Additional causes, or conditions, might also be introduced, which by their presence would probably affect the state of balance, such, for instance, as by dissolving in the liquid various salts or other substances.

Several of these causes, or conditions, may be modified, so as to alter the balance either in one or the opposite manner. Thus increased chemical corrosive power, a larger cathode, more free potassic cyanide, less argentic cyanide, or less strength of current alter the balance in one direction, whilst their opposites alter it in the contrary one.

Such experiments also show that the various conditions of the state of balance may either assist or counteract each other; that an increase of current is equivalent to a decrease of argentic cyanide, if the one is increased the other must be decreased in order to maintain the state of the balance; that an addition to the amount of free potassic cyanide, by diminishing resistance, is equivalent to an increase of current; that a decrease of cathode surface necessitates either a decrease of argentic cyanide or of current; that a rise of temperature is balanced by an increase of current; and so on.

All these influences have numerical values. In the experiments referred to it is shown that a rise of temperature of the liquid of 60 Fahr. degrees, *i.e.*, from 60° to 120° Fahr., is balanced by an increased strength of current from ·002306 to ·003282, or ·000976 ampere.

The arrangement and use of a depositing solution in such a manner constitutes a method of detecting the molecular influences of substances dissolved in electrolytes, and of determining to a certain extent their kind and amount of influences by their effect and degree of power in altering the "balance point" either in one direction or the opposite. It was found that the mere presence and admixture in solution of even a small quantity of argento-potassic cyanide in the above liquid altered the molecular arrangement of the free potassic cyanide in such a way as to diminish its power of alone transmitting the current into a silver cathode, and increased the tendency of the current to pass into the cathode partly by means of the double salt.

The phenomena of the "balance point" constitute also an interesting example of molecular equilibrium, in which the "balance point" may be compared to a ball suspended by an elastic cord and having attached to it a number of other similar cords in a state of tension, each drawing it in a different direction. In such a case an alteration of the degree of strain of any one of the cords changes that of all the others, and alters the position of the ball.

**Secondary Effects of Electrolysis.**—In very many cases the new substances actually observed at the electrodes are not those set free by the current, but are products or results of the action of those substances upon the liquid or upon the electrodes. Thus, when potassium is deposited from a solution of one of its salts into a cathode of mercury, the liquid in contact with the mercury becomes alkaline; when iodine is set free from the cathode in a solution of iodic acid, it is due to the deoxidising action upon the iodic acid of the hydrogen liberated there by the electrolysis of the water or of the iodic acid, and when it is set free at the anode during electrolysis of a solution of hydriodic acid it may be viewed as a direct result of the current or as a secondary result of liberated oxygen. The peroxide of silver formed at an anode of platinum in a solution of argentic nitrate may be viewed as a secondary product due to the action of the liberated oxygen or ozone upon the silver of the liquid. In many cases it is difficult to determine whether a liberated substance is due to primary or to secondary action.

Faraday advanced the view that "only those compounds of the first order are *directly* decomposable by the electric current which contain one atom of one of their elements for each atom of the other; for instance, compounds containing one atom of hydrogen or metal with one atom of oxygen, iodine, bromine, chlorine, fluorine, or cyanogen, whilst boracic anhydride ($BO_3$), sulphurous anhydride ($SO_2$), sulphuric anhydride ($SO_3$), iodide of sulphur, the chlorides of phosphorus ($PCl_3$ and $PCl_5$), chloride of sulphur ($S_2Cl$), chloride of carbon ($C_4Cl_6$), tetrachloride of tin ($SnCl_4$), terchloride of arsenic ($AsCl_3$), pentachloride of antimony ($SbCl_5$), are non-conductors of electricity, and incapable of electrolysis." I have observed that the decomposability of a salt depends upon the kind of liquid in which it is dissolved; *e. g.*, the iodide and bromide of antimony, both of which conduct and are decomposed when dissolved in acidulated water, do not conduct and are not decomposed when dissolved in carbonic bisulphide.

**Insoluble Coatings on Anodes.**—In many cases of electrolysis of aqueous solutions, the anode does not dissolve, but becomes coated with an oxide, chloride, fluoride, cyanide, sulplate, or other insoluble salt, usually by chemical union of the metal with an ingredient of the liquid. In this way silver in dilute hydrochloric acid becomes coated with argentic chloride; in a solution of argento-cyanide of potassium it becomes covered with argentic cyanide, lead in dilute hydrofluoric acid becomes coated with fluoride, and so on. In some cases the insoluble coating occurs not by corrosion of the anode, but by the oxygen evolved by electrolysis of the water, acting upon the ingredients of the solution; in this way various peroxides are formed. The formation of peroxides occurs upon platinum anodes in solutions of the nitrates of bismuth, silver, and lead; in certain alkaline solutions of lead, nickel, and cobalt, and in those of nitrate and acetate of manganese, and when the films which are thus formed are exceedingly thin their colours are in some cases very magnificent.

**Electrolytic Alloys.**—In many cases when metals are deposited upon metals, the two substances form alloys; grey antimony deposited upon mercury from a solution of tartar emetic alloys readily, but the black explosive variety does not. Tellurium deposited from a solution of its chloride upon platinum also forms an alloy. Boron, silicon, and lithium, when deposited from certain fused compounds upon a surface of platinum, also alloy with it. Hydrogen deposited upon palladium, or upon certain other metals, iron in particular, is absorbed, and imparts to the metal peculiar properties. In some cases the absorption of the deposited substance continues after deposition has ceased; this is only visible in cases where the deposited coating is extremely thin. A thin film of deposited copper is absorbed by zinc.

**Purity of Electrolytic Deposits.**—Not only do the deposited substances sometimes alloy with or penetrate into the mass of the cathode, but in some cases during the act of deposition they combine with some of the elements of the electrolyte, and are thereby altered in property. In this way antimony which has been rapidly deposited from a strongly acidified solution of its oxide in hydrochloric acid contains

Digitized by Google

several per cent. of the salt derived from the liquid, and possesses the very remarkable property that, if broken, or even scratched, it suddenly rises in temperature about six hundred Fahrenheit degrees; it also has the appearance of highly burnished steel, very widely different from the colour and appearance of the pure grey metal very slowly deposited from a feebly acidified solution of tartar emetic in dilute hydrochloric acid. This black antimony gradually loses its latent heat, explosive power, and brilliant appearance, in the course of one or two years, the period varying according to the thickness of the deposit.

It is only in certain cases and in the presence of a collection of suitable fortuitous conditions that a deposited substance is extremely pure; substances very easily deposited, such as hydrogen and copper, are usually so chiefly because it requires a stronger power to deposit most other bodies, also because in some cases the other easily deposited metals are precipitated as insoluble salts by ordinary chemical action. Thus lead in an acidified solution of sulphate of copper is precipitated as sulphate; similarly silver is precipitated in a solution containing a dissolved chloride. All deposited substances are, of course, more likely to be pure the greater the degree of purity of the liquid.

**Divided Electrolysis.**—When an impure liquid or a mixture of solutions is electrolysed, either a single substance alone may appear at the anode or cathode, or several may be simultaneously liberated. With a feeble current and large electrodes one substance alone may appear at either electrode, but by either increasing the strength of the current or diminishing the size of the electrodes, a second, or even a third substance may be liberated, the current appearing to divide its action amongst the various compounds present. The least electro-positive cation is usually liberated first, and the more positive ones subsequently as the current strength is increased. In all cases weaker affinities appear to be overcome first; but this is only a superficial explanation, the true one being much less simple. By employing proportions of the substances, larger as their electro-positive property in the particular liquid is greater, several may be simultaneously deposited, or the more positive ones may be deposited even in larger amount than the less positive ones, as for instance potassium from moist potassic hydrate. It is by obeying these and other conditions that alloys and mixtures of substances are usually set free at the electrodes. The order of degree of electro-positive state of the metals desired to be deposited may in most cases be ascertained by connecting the metals in pairs with a galvanometer, immersing their free ends in the liquid, and observing the direction of deflection of the needles.

In electrolysing a mixture of the sulphates of zinc, cadmium, and copper, Favre succeeded, by altering the conditions of the experiments, in obtaining at will, either one, two, or all the three metals simultaneously; and states that the results of the operation vary, 1st, with the voltaic energy of the battery; 2nd, with the electrolytic resistance of the salts; 3rd, with the relative quantity of each salt; and 4th, with the greater or less rapidity of the electrolysis, which can be regulated. He concludes that by varying these conditions we are enabled to withdraw from a mixture of salts the different metals in succession, and thus proposes an electro-chemical analysis. (*Comptes Rendus*, Vol. LXXIII.; *Journal Chemical Society*, Second series, Vol. X., p. 113). This proposal, however, is not a new one.

(TO BE CONTINUED).

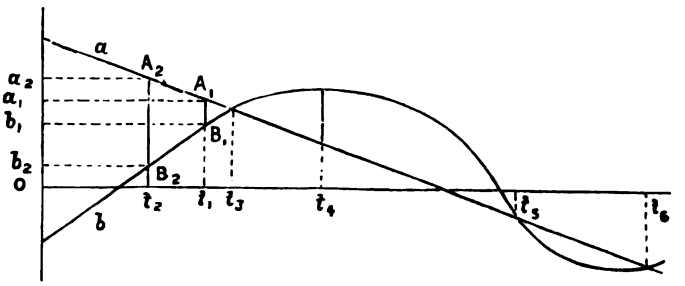
## CURRENT ENERGY.—X.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 559, VOL. XI.)

The thermo-electric diagram is a most valuable aid to an intelligent comprehension of the subject, and gives one rapidly a general view of the relative magnitudes and the directions of the E.M.F's. in different parts of a linear circuit, whether of two or more metals, and especially so when the neutral temperature of two metals is within the range of temperature concerned.

Referring to the same diagram, in which the thermo-electric powers of two metals $a$ and $b$ are represented by the lines $aA_2A_1$ and $bB_2B_1$, of which the former is straight, and the latter, for the sake of generality, is supposed to be curved in part of its course, and also to change curvature so as to cross the line of $a$ once in its straight portion and twice later at the higher temperatures $t_5$ and $t_6$, we have, when the two metals are paired to form a circuit, and their junctions kept at temperatures $t_1$ and $t_3$, the Peltier junction forces represented in magnitude by the rectangular areas $A_1B_1b_1a_1$ and $A_2B_2b_2a_2$, their directions in the circuit being respectively from $A_1$ to $B_1$ at the hot, and from $A_2$ to $B_2$ at the cold junction, *i.e.*, both downwards in the figure from



the metal of higher to that of lower power. And, in addition, we have the Thomson E.M.F.'s in the separate conductors, owing to their ends being at different temperatures, whose integral amounts are represented by the areas $A_1A_2a_2a_1$ and $B_1B_2b_2b_1$, and whose directions are, as before for the Peltier forces, downwards in the figure, viz., from $A_2$ to $A_1$ in $a$ (cold to hot), and from $B_1$ to $B_2$ in $b$ (hot to cold). And their resultant is the complete E.M.F. in the circuit, represented by the area $A_1B_1B_2A_2$ acting so that the current is from $a$ to $b$ at the hot junction, and its direction round the circuit therefore similar to that of the motion of the hands of a watch.

These areas, by means of the relation energy = E.M.F. × quantity (a relation whose meaning cannot be too carefully studied by those who think electricity is energy, and by those who conclude that E.M.F. is a form of energy, both of which views have their exponents), may also indicate the amounts of heat absorbed or generated in the circuit during the passage of the unit quantity of electricity, as the unit current for one second, or $1/n$ of the unit current for $n$ seconds. At the hot junction, the current and the Peltier force there situated are similarly directed, and the area $A_1B_1b_1a_1$ shows the amount of heat absorbed there (difference of power of $a$ and $b$ multiplied by the temperature), *i.e.*, disappearing as heat and passing into the form of current energy, which latter is not to be confounded with the heat "frictionally" developed, which is energy dissipated. At the cold junction the current is against the Peltier E.M.F. there; hence the area $A_2B_2b_2a_2$ shows the amount of heat generated there passing from current energy into heat—not, however, in the frictional manner, irreversibly, but so that the generation becomes an absorption when the current is reversed. And in the substance of both conductors the current goes with the E.M.F., and hence the corresponding areas both represent heat absorbed.

But as regards these last E.M.F.'s, the diagram does not in any way indicate their distribution in the wires, but only their integral amounts, reckoned from end to end of the wires, depending on the terminal temperatures. Hence, the Thomson reversible heat effect, in $a$ for example, may be very different in its distribution, according to the manner in which the temperature varies along the wire. If, for instance, the whole wire $a$ and the whole wire $b$, except their portions close to the hot junction, be kept at or near the temperature of the cold junction, it is evident that the Thomson forces must be pretty nearly all collected near the hot junction, where the temperature of the wires falls rapidly. Or if we greatly raised the temperature of the middle part only of one of the wires, we should introduce two opposed E.M.F.'s of equal amounts, one each side of the place of maximum temperature, of greatest intensity where the temperature varied most rapidly. But, provided the terminal temperatures are the same, the integral E.M.F. and integral

Digitized by Google

reversible heat effect in the wire are unaffected, and it is these alone of which the thermo-electric diagram takes cognisance, irrespective of the actual manner of variation of temperature between the given extremes.

The net result is that there is an absorption of heat per unit of electricity passing, whose amount is represented by the area $A_1B_1B_2A_2$ enclosed by the lines of the two metals, and by the vertical lines corresponding to their junction temperatures. It is the excess of the heat absorbed over that generated reversibly, and is accounted for by Joule's law as frictional heat in the whole circuit, distributed in proportion to the resistance of the different portions. And, of course, considering the areas to represent the E.M.F.'s, this area $A_1B_1B_2A_2$ is the complete thermo-electric force in the circuit, which, along with the resistance, determines the strength of current, provided there are no other E.M.F.'s acting.

So far as the four component E.M.F.'s are concerned, the above statements regarding reversible heats per unit of electricity do not require any alteration when the current passing is not that due to the thermo-electric forces alone, but also to some other E.M.F., as of a galvanic cell in the circuit; with this reservation, that if the cell should reverse the current, the former absorptions of heat now become generations, and the former generations become absorptions, whilst the frictional heat per unit of electricity passing is now numerically equal to the excess of the cell's E.M.F. over that of the thermo-electric pair.

Dismissing now the borrowed galvanic cell, and considering thermo-electric forces alone, we may observe the effect produced by the powers of two metals becoming equal at a certain temperature. In the previous, both the junction temperatures were below $t_3$, the first neutral temperature. But, keeping the cold junction at the same temperature $t_2$, if we raise the temperature of the other above $t_3$, the Peltier force at the latter vanishes and reappears reversed, acting now from $b$ to $a$. The complete E.M.F. reached its maximum at $t_3$, and is consequently thereafter reduced, and this will go on until the areas to right and left of the neutral point are equal, when the higher temperature is $t_4$. But we may accelerate this by warming the cold junction, and have zero current for any number of pairs of temperatures between $t_2$ and $t_4$, one below $t_3$ and the other above. Starting with both junctions at the neutral temperature itself, the effect of either heating or cooling one of them is to produce a current in the *same* direction. With both junctions above $t_3$ (or, more strictly, between $t_3$ and $t_5$, so as not to include a fresh crossing point), we again have only a single area to deal with, as when both were below $t_3$, though now the direction of current is reversed, from the line of the metal $b$ being above instead of below that of $a$.

That one of the lines of power becomes curved (and it would be the same if both were curved) does not alter the method of reckoning the complete E.M.F. by the area enclosed between the lines of power and the verticals at the terminal temperatures. And obviously the Peltier forces, being always represented by rectangles, require no modification of treatment. But it is somewhat different with the Thomson force in $b$, the metal with curved line of power. For, draw a horizontal straight line from any point of the $b$ line to the vertical through O, such as $B_2b_2$, and let its end $B_2$ travel along the $b$ line, keeping always parallel to itself. The area it sweeps out between any two temperatures (as $B_2B_1b_1b_2$ between temperatures $t_2$ and $t_1$) measures the Thomson E.M.F. within that range in the metal $b$, so long as the horizontal line moves continuously either upward or downward; the E.M.F. being from hot to cold when it moves up, and from cold to hot when down. But when the line of power is curved, it may move up in one part of its course, and down in the rest; thus, if the junction temperatures are $t_3$ and $t_5$, it will move up to $t_4$, and thereafter down. In this case we must take the excess of the area swept out in the second part of the motion over that in the first to represent the Thomson E.M.F., which is from cold to hot. On the other hand, the Thomson E.M.F. in $a$ between the same temperatures, also from cold to hot, requires no special treatment. As there are no Peltier forces, the complete E.M.F. equals the difference of the two Thomson E.M.F.'s, and this is simply the area bounded by the straight $a$ line and the curved $b$ line, the terminal verticals being non-existent. This example is curious from the complete absence of the junction forces and reversible heat effects there, such being confined to the interior of the metals. But a much more curious case was pointed out by Professor Tait, which may be readily understood from the diagram, viz., that in which a thermo-electric current is kept up in a circuit of two metals solely by the Thomson E.M.F. in one of them, there being thus absorption of heat in some parts with generation in other parts of the one, but no reversible effect at either junction or in the other conductor. Thus, pair the metal $b$ and the standard metal whose line of power is the base line $Ot_6$, and keep their junctions at the temperatures at which the line $b$ crosses the base line, the two neutral points of $b$ with respect to the standard. Then we have no junction forces, and no force in the standard metal, but a large Thomson E.M.F. in the metal $b$.

When there are more than two metals in a thermo-electric circuit, the diagram naturally becomes more complex. The terminal temperatures of any wire being given, that portion of its line of power between these limits must be selected, and the same done for all the other wires. These detached lines must now have their ends joined by verticals in the proper order, thus making a closed circuit. The temperature and thermo-electric power are cyclic in the real electric circuit—*i.e.*, starting from any point, and going once round the circuit, they come back to their old values. Similarly in our closed diagram the power is cyclic, varying gradually with change of temperature in those portions made up of the lines of power of the different metals, and abruptly at the verticals, corresponding to the passage from one metal to another without change of temperature. Should there be no crossing of lines, the area bounded by our closed "curve" (in the general sense) gives us at once the complete E.M.F. If there are crossings, some areas will have to be reckoned negatively, and very curious complications may occur, as may be seen by inspection of a complete thermo-electric diagram for all the metals, with a considerable number of neutral temperatures of pairs of metals within a given range of temperature.

The method of reckoning the magnitude of the Thomson E.M.F. in a metal by the area swept out by a horizontal line, as above described, one end of which moves along the line of power, would be no longer correct if our horizontal base line were taken to represent the line of power of a metal in which the "specific heat of electricity" is not *nil*. Therefore, if no metal could be found in which there was no reversible heat effect, it would be highly convenient to imagine there to be one, and this imaginary standard metal would do quite as well as a real one. It is, however, satisfactory to know that there is a metal that fulfils the condition, or nearly so, viz., lead, in which the specific heat of electricity is *nil*, or very small, as found by Le Roux. Lead is therefore the appropriate standard metal whose line of power is the base line $Ot_6$.

No other metal has been found having this property, but some of Professor Tait's alloys of platinum and iridium answer the description. Their lines of power are therefore parallel to the base lead line, and the complete E.M.F. in a circuit formed of two of them, or of one of them and lead, is represented by a rectangle, being simply proportional to the difference of junction temperatures, current thus varying as difference of temperature. Such arrangements are most appropriate for measuring temperatures.

The lines of most of the metals are straight within wide ranges of temperature. This, which is remarkably convenient for the numerical calculation of thermo-electric forces, proves that the specific heat of electricity varies in general as the absolute temperature. For, the equation of a straight line being linear, let $p = r + st$ express the power of any metal referred to lead in terms of the temperature $t$, where $r$ and $s$ are two constants. Then $\sigma$, the specific heat of electricity for that metal, being the E.M.F. from cold to hot per unit rise of temperature, must equal $-st$, or vary as the temperature. The constant $s$, depending on the nature of the metal only, that is, having no relation to what other metal it may be

Digitized by Google

joined with to obtain a thermo-electric current, is positive for those metals whose specific heats of electricity are negative, and conversely. In fact $s$ = tangent of angle between the line of the metal referred to and the lead line, positive when it slopes up from left to right, whereas the Thomson force under the same circumstances is directed downwards. As for the constant $r$, it represents what the power referred to lead would be at the zero of absolute temperature, — 273°C, if the lines of lead and the metal concerned continued straight all the way to that limit. But when the line of a metal is curved, $s$ is, of course, no longer independent of the temperature. Thus, in the figure, the value of $s$ for the metal $b$ changes from positive to negative at temperature $t_4$, and becomes positive again later. It is not likely that $s$ keeps quite constant for any metal if sufficiently heated so as to appreciably change its structure (as by softening it), and it certainly varies greatly in iron and nickel, as regards the former of which Professor Tait found that its line of power became sinuous at high temperatures. But iron is anomalous in its behaviour in various other respects, as are the other magnetic metals, so we may expect anomalous thermo-electric behaviour.

The following are the formulæ for the component E.M.F.'s and their resultant in a circuit of two metals $a$ and $b$. Let $p_a$ and $p_b$ be their powers with respect to lead at temperature $t$. Then

$$p_a = r_a + s_a t, \qquad p_b = r_b + s_b t,$$

where $t$ is the absolute temperature, and $r$ and $s$ are constants. Put $a$ in contact with lead, the junction E.M.F. is $p_a t$, the power multiplied by the temperature; thus

$$P_a = t\,(r_a + s_a t), \qquad P_b = t\,(r_b + s_b t),$$

$P_a$ and $P_b$ being the contact forces with lead.. Put $a$ and $b$ in contact; their relative power is $p_a - p_b = p_{ab}$ say, or

$$p_{ab} = (r_a - r_b) + (s_a - s_b)\,t = (r_{ab} + s_{ab}\,t),$$

and therefore the contact force from $a$ to $b$ at temperature $t$ is

$$P_{ab} = t\,(r_{ab} + s_{ab} t) \quad . \quad . \quad . \quad . \quad . \quad (1)$$

In the circuit formed of $a$ and $b$ with junctions at temperatures $t_1$ and $t_2$ ($t_1$ being the higher) there are two contact forces whose values are found by giving $t$ successively the values $t_1$ and $t_2$ in the last formula. Both being from $a$ to $b$ their difference constitutes the acting E.M.F. arising from contact force. This is,

$$r_{ab}\,(t_1 - t_2) + s_{ab}\,(t_1^2 - t_2^2) \quad . \quad . \quad . \quad . \quad (2)$$

Next let $T_a$ and $T_b$ be the Thomson forces in $a$ and $b$. Then since $T_a = \int_{t_2}^{t_1} \sigma_a\,dt$ from cold to hot, and $\sigma_a = -s_a t$,

$$\left.\begin{aligned} T_a &= \int_{t_2}^{t_1} s_a t\,dt = \tfrac{1}{2} s_a\,(t_1^2 - t_2^2) \\ \text{and similarly} \quad T_b &= \tfrac{1}{2} s_b\,(t_1^2 - t_2^2) \end{aligned}\right\} \text{both from hot to cold.} \quad (3)$$

Adding together the two Peltier forces and the two Thomson forces, and attending to the signs so that when the sum is positive the current is from $a$ to $b$ at the hot junction, we find the complete E.M.F. to be

$$E_{ab} = (t_1 - t_2)\,(r_{ab} + \tfrac{1}{2}\,(t_1 + t_2)\,s_{ab}) \quad . \quad . \quad . \quad (4)$$

which can, of course, be obtained directly from the formula

$$E_{ab} = \int_{t_2}^{t_1} p_{ab}\,dt \quad . \quad . \quad . \quad . \quad . \quad (5)$$

which is Sir W. Thomson's general formula (before obtained), applicable whether the lines of power are straight or curved. Equation (4) may be written

$$E_{ab} = -\,s_{ab}\,(t_1 - t_2)\,(t_{ab} - t_o)$$

where $t_o$ is the mean temperature of the junctions, and $t_{ab}$ the neutral temperature. But for numerical calculation of the E.M.F. of a thermo-electric pair (4) is most convenient. *I.e.*, multiply the difference of relative power at the mean temperature by the difference of temperature. A table of the values of the constants here called $r$ and $s$ is given in Everett's "Units and Physical Constants."

(TO BE CONTINUED.)

## THE EVOLUTION OF DYNAMO MACHINES.—III.

BY JOHN T. SPRAGUE.

(CONTINUED FROM PAGE 33.)

24. In Section 21, and Fig. 8, it was shown that as a consequence of the linear electric stress, transversal rings of magnetic order are formed at right angles; therefore, from the normal relations of magnetic and electric force, we must expect that when *lines of magnetic* stress are formed, as in the magnetic field, they must develop *rings of electric order*, closed circles of electric polarisation forming sections of the field. This is also a result of the magnetic theory (illustrated Fig. 9, p. 537, Vol. X.), and it follows that the molecular distinction between electric and molecular polar order is that, if we consider the electric stress as being the active cause, and resulting in a consecutive arrangement of the + and — ends of molecules, the *electric* rings under consideration must consist of molecules thus arranged, while the *magnetic* rings consist of molecules ranged side to side, with the electric lines passing through them at right angles to the plane of the ring. It is desirable to clearly exhibit this now, in order to trace the action which occurs in a wire when it enters the magnetic field.

25. Fig. 11 represents a bar magnet, N S, with one of its *rings* of electro-static order formed on the magnetic *lines* of force issuing from its N pole. C is a conductor carrying a current, such as the ring of Fig. 9, 1 in Section 22; its magnetic lines, shown by the arrows, agree with those of N S, and

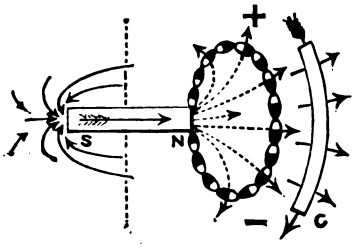


FIG. 11.

the result is to draw the wire to the middle line of the magnet, where the sum of the agreements is greatest. In these conditions the current and magnet unite; the space within the wire becomes part of the magnet, and the return lines of force would be to the outside of the wire, where they would also agree with its lines. But if there were no current in C, a different set of conditions would come into play. The full field cannot be drawn so as to be intelligible, but a little consideration will show that the space around the magnet is filled with circles, such as that shown, of all diameters, so that the wire will be constantly entering fresh circles as it approaches the pole N, which circles will have their magnetic lines in different directions, so the molecules of the wire will be solicited in constantly changing directions in order to accommodate themselves to these changing conditions.

26. Following out these ideas, Figs. 12 and 13 will show what happens when a wire crosses the lines of force of a

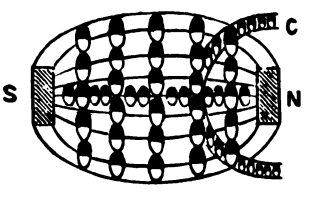

FIG. 12.

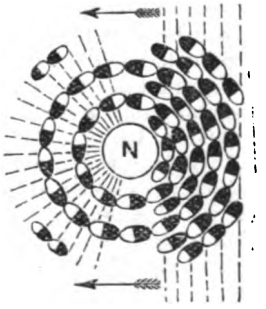

FIG. 13.

magnet. In Fig. 12 we have the vertical section of the field of a N and S pole, as between the poles of a horseshoe, or those of a dynamo-machine, showing the lines of magnetic

Digitized by Google

force, with the resulting electric rings in section. The wire C shows part of a circle coming down upon the pole, as in Fig. 11, or of a wire simply crossing the field between the poles, with its molecules forming part of the rings they enter. We can see at once why a wire ring descending between the poles would have no current set up in it, because the two sides would be oppositely polarised, while a current could be obtained from its opposite ends by both actions uniting as they do in the Gramme ring.

Fig. 13 is a section of the same field, in which we can see what occurs in a wire traversing it in the direction of the arrows; as it occupies the several vertical dotted lines, it cuts circle after circle, in each of which there is a different angular relation to the wire, necessitating a rotation of the molecules in a spiral line around the wire. Here we may find an explanation of what occurs in ring armatures of the Gramme and Siemens types.

27. Such a field as is shown in Fig. 12 may be regarded a bar magnet without external lines. Therefore, when a helix occupies this field, its wires correspond to the several circles shown, and the molecules must form a continuous electric polar chain, and perform a spiral motion in taking up that position.

If the helix contains an iron core it concentrates the lines of force more speedily and more completely, so that Fig. 12 may give a conception of what occurs in bar armatures passing between field poles.

28. *Current as a Spiral Molecular Rotation.*—The actions thus studied appear to indicate that electric current is not propagated in a direct line along the conductor, but in a spiral winding round the conductor corkscrew fashion. Such a

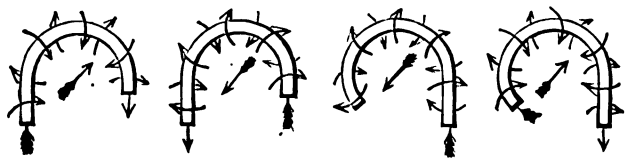

Fig. 14.

spiral progress of apparently linear motion is found in other cases; in a vibrating metal rod giving out a musical note, a loose ring of paper comes to rest on the nodal points of the bar, and these form a spiral line around the bar. The phenomena of polarised light indicate that the undulations take place in all planes, which corresponds to a spiral propagation, just as a corkscrew, looked at edgeways, appears as an undulating line, and is really such a line undulating in all planes. Professor Hughes's latest examinations of the phenomena of magnetism demonstrate the existence of this spiral molecular arrangement, rather than a direct polar order. The subject is not ripe for any very definite opinions, but I offer Fig. 14 as very suggestive.

Assuming that a "positive" current implies a right-handed rotation in the wire, we have an obvious cause for the direction of the magnetic circles corresponding to it. For this purpose it is of no moment which is the actual direction corresponding to the + current, because our making the point of the arrow correspond to the north pole is purely arbitrary.

It will be seen that in Fig. 14, 1 and 2 are the front turns of a right-handed helix, with the current in the two directions, while 3 and 4 are the same for a left-handed helix. One and 4 also show why a right-handed helix is the same thing as a left-handed helix at the other end, with current reversed, and therefore the same magnetisations, for 2 and 3 show that they are exactly alike as to the direction of their action.

29. *Field Magnets.*—There is little difference of principle in this portion of dynamo machines, different as they are in appearance. The earlier forms were mere horseshoe magnets to which variously formed pole pieces were afterwards attached, so as to act on the different kinds of armatures used. In the late machines the same horseshoe is produced, though usually in the form of two opposed horseshoes forming consequent poles in a complete metallic circuit, which gives strength to the framework of the machine. Here also projecting pole pieces are added to carry the poles around so much of the armature as is necessary, the extent of the projection depending upon the nature of the armature. There are two plans in use which look different, yet are alike in principle. Fig. 15 shows the two opposed horseshoes let into common pole pieces, with projecting horns, N S, forming the circular field in which the armature rotates. This is the general type of the Gramme field magnets. Fig. 16 shows the pole piece, and one arm of each horseshoe formed in one mass of metal, two such bars being

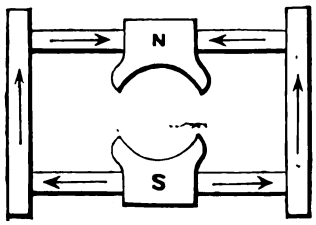

Fig. 15.

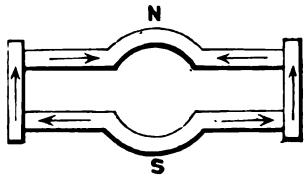

Fig. 16.

secured to the cross pieces to complete the system. This is the type of the Siemens field magnets, in which the arms are made of a number of parallel bars of wrought iron curved to the required shape. The same type is employed in the Bürgin machine, but made of solid castings, and also in the Maxim and other machines.

30. It is evident that these field systems have no different action from that of the single horseshoe with poles forming a circular field partly enclosing the armature, as employed with the earliest form of Siemens' ⊥ core. In fact, it is only in the mode of generating the field force that there is any difference of principle in the different forms employed, or any evolution of form growing to a higher type. But in this we may trace a line of development having definite aims, (1) to concentrate the highest possible force upon the exact spot where it is most useful, (2) to control that force to its required work.

## LECTURES ON ELECTRICAL ENGINEERING.

The Council of the Society of Engineers have arranged for a series of lectures on "Electrical Engineering," to be delivered in the society's reading room, 6, Westminster-chambers, S.W., during the winter session. The fee for the course is £2 2s. for non-members, and £1 1s. for members or associates of the society. The lecturer will be Mr. John C. Fell, Professor of Electrical Engineering in the City of London College. The dates of the lectures are as follow :—Lecture I. (January 7) : Electricity, Mechanical Theory, Magnetism, Electro and Permanent Magnets, Inductive Discharge, Spark Igniters, and character of the Current. Lecture II. (January 14): Galvanic Electricity, Commercial Galvanic Batteries, Varieties, Arrangement of Batteries for Maximum Effect, Internal Resistance, Electrolysis, Electro-plating. Lecture III. (January 21): Dynamo-Electricity, Current Generation, Units of Current Strength and Resistance, Dynamo-Electric Machines, Varieties, Modern Improvements. Lecture IV. (January 28): Electric Arc Lights, Varieties, the Gramme, the Weston, the Brockie, the Brush, &c., Automatic Adjustments, Heating and Lighting Effects of Current, Conductors and Dielectrics. Lecture V. (February 11) : Electric Incandescent Lights, Varieties, the Edison, the Swan, &c., Current Resistances, Sub-divisions of Current, the Filaments, Shunts, Safety Junctions. Lecture VI. (February 18): The Electric Motor, Essential Principles, Varieties, the Siemens, Ayrton and Perry's, Modes of Application, Electrical Haulage, the Transmission of Electrical Power. Lecture VII. (February 25): The Accumulator, Secondary Batteries, Varieties, the Faure, &c., Applications to Electric Lighting, to Launches, Railways, and Tramways, Ammeters, Volt-meters, &c. Lecture VIII. (March 10): Thermo-Electricity, Direct Conversion of Heat into Work, Thermopiles, Telephony, the Gower-Bell, the Edison, Transmitters and Receivers, &c.

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 43).

### CHAPTER V.—TELEGRAPHS (CHEMICAL) BASED ON DYNAMIC ELECTRICITY.

Awhile forbear,
* * * * * *
Nor scorn man's efforts at a natural growth,
Which in some distant age may hope to find
Maturity, if not perfection.
*Household Words*, June 14, 1851.

#### 1811.—SCHWEIGGER'S TELEGRAPH.

In preparing an account of Sömmerring's telegraph for insertion in his *Journal für Chimie und Physik* (II. 240, for 1811), Schweigger of Halle—the same who afterwards invented the galvanometer—was struck with the insuperable difficulty there would be in dealing practically with so many wires, and in his paper he suggested a plan which required only two wires, and two piles of different strengths, so that at one time the weaker may be used, and at another time the stronger, or even both combined. In this way the quantity of gas produced in a given time at the distant station would be varied, a small quantity denoting one letter, and a larger another. Again, by changing the direction of the current as in Salvá's telegraph, and by varying the duration of the evolutions, other letters might be indicated; and thus, by the combination of these primary elements of quantity and time, all the letters of the alphabet could be expressed through two wires instead of thirty-seven.

Schweigger also proposed, in the same paper, to print the signals on paper covered with red lead, or lamp black, in a way nearly resembling that followed by Wheatstone in his patent of 1841; and, in ignorance of Sömmerring's alarum, suggested the firing of Volta's gas-pistol by Leyden jars as a means of drawing attention.

#### 1813.—SHARPE'S TELEGRAPH.

All that we know of this invention is contained in the following paragraph which we copy from the *Repertory of Arts*, 2nd Series, June, 1816, page 23:—

"On the Electrical Telegraph.
"Communicated by Mr. J. R. Sharpe,
of Doe Hill, near Alfreton.

"In the *Repertory of Arts*, Vol. XXIV., Second Series, p. 188, is an account of an electric telegraph by M. Soemmering. This account I did not see till a few weeks ago. Without the slightest wish to throw a doubt over the originality of M. Soemmering's invention, I beg leave to mention that an experiment, showing the advantages to be obtained from the application of the certain and rapid motion of the electric principle through an extensive Voltaic circuit to the purposes of the ordinary telegraph, was exhibited by me before the Right Hon. the Lords of the Admiralty, in the beginning of February, 1813."

My Lords are said to have approved the design, but passed it over with the remark that "As the war was over, and money scarce, they could not carry it into effect." (*Saturday Review*, August 21, 1858, p. 190).

A nephew of the inventor, writing in 1861,† says, in reference to the above announcement, that Mr. Sharpe "conveyed signals a distance of seven miles under water." In the hope of getting further information we addressed ourselves to this gentleman, but, unfortunately, he could add nothing to the above-mentioned facts.

Mr. J. R. Sharpe was bred in London as a solicitor, but early left the profession, and retired to Doe Hill, which he built in 1801. He was always of a studious turn, and even in advanced age amused himself with mathematical problems. He died November 11, 1859, aged 84 years.

It was, probably, *anent* Sharpe's proposals that the following squibs were written, which we extract from *The Satirist*, September and October, 1813.

"On the report that it is in contemplation to substitute an electrical mode of communication with the outposts (by means of wires laid underground) for the existing telegraphic system:—

"Our telegraphs, just as they are, let us keep,
They forward good news from afar,
And still may send better—that Boney's asleep,
And ended oppression and war.
"Electrical telegraphs all must deplore,
Their service would merely be mocking;
Unfit to afford us intelligence more
Than such as would really be *shocking!*
"Tam Glen."

"On the Proposed Electrical Telegraph, October, 1813.

"When a victory we gain
(As we've oft done in Spain)
It is usual to load well with powder,
And discharge 'midst a crowd
All the Park guns so loud,
And the guns of the Tower, which are louder.
"But the guns of the Tower,
And the Park guns want power
To proclaim as they ought what we pride in;
So when now we succeed
It is wisely decreed
To announce it from the *batteries of Leyden*"

#### 1816.—COXE'S TELEGRAPH.

In February, 1816, Dr. J. Redman Coxe, Professor of Chemistry at Philadelphia, published some suggestions for an electro-chemical telegraph on the same principle as those already described. His views are given in the following letter, which we have extracted from Thomson's *Annals of Philosophy*, Vol. VII., pp. 162—3, headed "Use of Galvanism as a Telegraph:"—

"I observe in one of the volumes of your *Annals of Philosophy* a proposition to employ galvanism as a solvent for the urinary calculus, which has been very properly, I think, opposed by Mr. Armiger. I merely notice this, as it gives me the opportunity of saying that a similar idea was maintained in a thesis three years ago by a graduate of the University of Pennsylvania.

"I have, however, contemplated this important agent as a probable means of establishing telegraphic communication with as much rapidity, and, perhaps, less expense than any hitherto employed. I do not know how far experiment has determined galvanic action to be communicated by means of wires, but there is no reason to suppose it confined as to limits, certainly not as to time. Now, by means of apparatus fixed at certain distances, as telegraphic stations, by tubes for the decomposition of water and of metallic salts, &c., regularly arranged, such a key might be adopted as would be requisite to communicate words, sentences, or figures, from one station to another, and so on to the end of the line. I will take another opportunity to enlarge upon this, as I think it might serve many useful purposes; but, like all others, it requires time to mature. As it takes up little room, and may be fixed in private, it might in many cases, of besieged towns, &c., convey useful intelligence with scarcely a chance of detection by the enemy. However fanciful in speculation I have no doubt that sooner or later it will be rendered useful in practice.

"I have thus, my dear sir, ventured to encroach upon your time with some crude ideas that may serve perhaps to elicit some useful experiments at the hands of others. When we consider what wonderful results have arisen from the first trifling experiments of the junction of a small piece of silver and zinc in so short a period, what may not be expected from the further extension of galvanic electricity? I have no doubt of its being the chiefest agent in the hands of nature in the mighty changes that occur around us. If metals are compound bodies, which I doubt not, will not this active principle combine their constituents in numerous places so as to explain their metallic formation; and if such constituents are in themselves aeriform, may not galvanism reasonably tend to explain the existence of metals in situations in which their specific gravities certainly do not entitle us to look for them?"

Dr. Coxe does not appear to have ever reduced his ideas to practice, but the large faith which he expresses in the capabilities of galvanism deserves to be remembered to his credit. Indeed there can be no doubt that, if electrical science had made no further advances, the early projects that we have been describing in this chapter would have gradually developed themselves into practical electro-chemical telegraphs, such as were afterwards proposed by E. Davy in 1838, by Smith in 1843, by Bain in 1846, and by Morse in 1849.* But the grand discovery of electro-magnetism was at hand, and soon turned the tide of invention into quite another channel.

(TO BE CONTINUED.)

* The author reserves all rights of translation.

† A Treatise on the Construction and Submersion of Deep-Sea Electric Telegraph Cables," by Benjamin Sharpe, London, 1861, page 16.

* Besides all these inventions, other electro-chemical telegraphs have been proposed by Bakewell, Caselli, Bonelli, D'Arlincourt, Sawyer, and others. All are dependent on a fact which, as we have shown in our fourth chapter, was first observed by Cruikshank in 1800, very soon after the announcement of the voltaic pile, viz., the power of electricity to discolour litmus paper.

W. SCOTT ELLIOTT.—*We may yet give a description of the battery you mention, if the necessary details are to be obtained, which we doubt. Our opinion as to the efficiency of primary batteries for lighting purposes is expressed in another column. Thanks for the paper.*

## ELECTRICAL RAILWAYS.

It has been the lot of almost all discoveries and inventions to be thought mere playthings at first. People who are content with small beginnings do not despair on this account. Inventors and discoverers are usually a sanguine race, and what they may think they foresee or venture to predict of their work does not often count for much. But in very many cases their most confident anticipations have fallen far short of the ultimate realisation. This was the case with the steam locomotive, the steam packet, and the electric telegraph. They were regarded as remarkably curious, but not as remarkably valuable—things which might develop into utilities some day, but which for a long while must remain mere toys. So with the electric light, so with the telephone, both of which have only recently—though with greatly differing rapidity of growth—risen to the practically useful stage of existence. For a long time past electric locomotion, both on land and water, has been known to be possible, and experimental proofs have been made public on many occasions, but nothing further ever came of them. They were little better than toys, it was thought, and they have remained so almost until now. Recent successful applications of electricity in other fields, however, have lent much encouragement to toys in general and to electrical toys in particular, so that the electrical launch, the electrical tram, and the electrical railroad are now on their trial, not as objects of wonder, but as possibly capable of superseding some of the appliances of a similar class now worked by steam or horse-power.

One such practical experiment in that direction was fully described in our account of the electrical railway—if we may dignify it by that title—started on the Brighton sea beach some months ago. It was a diminutive affair, and considered from the point of view of the yard measure it is so still; but, looked at in the broader aspect of future possibilities, it is a very big stride towards the accomplishment of far greater things. The railway referred to, we may remind our readers, is a quarter of a mile in length, and the rolling stock consists of one car only, capable of carrying a dozen passengers. But it does carry them—carries them without being pushed up behind, and, so far, neither the passengers nor proprietors have had to get out in order to let the wheels go round. Its dead weight consists only of a small motor no heavier than what would be necessary in any case for steadiness on the rails. An inexpensive generator and economical gas engine at a fixed point supply all the needful power, and a guard completes the equipment, this latter being required more for toll-collecting than for "driving." Having started the gas engine he has, in fact, nothing to do but to jump on the car and ride there and back, his duties being merely to take the tickets and shut off the current, the engine and generator being left to take care of themselves. Happily the experiment has proved a very inexpensive one, the number of people who, either for business or pleasure, patronise the "line" being greater than was expected. The traffic has averaged some 2,300 passengers weekly during the whole period, which may be called a paying business, considering the inexpensive character of the plant. The track consists of a pair of rails only two feet apart and lightly laid down, its total cost of construction, and that of the whole plant, being probably more than covered already by the takings.

Some very valuable facts, no doubt, will be evolved from the practical working of this little railroad at Brighton. The capabilities of generator and motor for lines of given length, the engine power required, and the general working expenses, are points which have now been determined with tolerable accuracy for the guidance of future experimenters. The cost of the gas consumed, it is said, has not exceeded ten shillings a week, and this, therefore, together with guard's wages and wear and tear, represents the working expenses. The original outlay is not likely to deter fresh adventures, and we confidently expect they will be tried under different conditions elsewhere. For the moment they seem mainly to serve the amusement of the public, but in reality they are establishing the practicability of electric locomotion on a larger scale, and for more serious uses. The immediate value of the electric railroad at Brighton is that it has proved pecuniarily a success; and the fact will, no doubt, lead to its introduction at other watering places which are peculiarly suited for this kind of trial. Many of our seaside resorts have a long sea frontage and a beach quite suitable for the kind of railroad required. The ordinary foot-traffic is not interfered with; the lines are almost imperceptible; the danger is *nil*, and nobody complains about a nuisance. There is no smoke, no noise, nor in fact any of those objectionable fea-

Digitized by Google

tures which have to be endured where steam railways intrude themselves. When the summer holidays are on, the novelty of the conveyance is of itself sufficient to attract custom; some of our watering places have "seasons" lasting longer than the summer, and at several there are points between which a railway of this description would be a boon to foot passengers over and above that to the "pleasure trip" parties. We have already seen this form of locomotive turned to more serious use at Portrush by the eminent electrician who has just been removed from amongst us. Water-power, strange to say, is seldom available at the seaside, though we know of one remarkable and much-frequented spot on the south-west coast where the power of two fierce torrents runs uninterruptedly to the ocean. But gas is always to be had, and for work of this kind gas appears to be both cheap and efficient. We see no reason why the public should not pay for these experimental operations, and if they can be induced to do so under circumstances such as we have witnessed at Brighton, all the parties concerned will profit by it—the public having its enjoyment at a trifling cost, the scientist conducting an experiment at no serious loss.

## PRIMARY BATTERIES FOR ELECTRIC LIGHTING.

The question often arises, though it is seldom answered, how much is the general public prepared to pay for electric lighting? We know that as shareholders in companies they have in some cases had to pay dearly enough; but it is rather to the light as a luxury, purchased and maintained at a price, that we refer. When electric lighting in houses has become general everybody will criticise cost as much as they now do the price of gas. But electric lights in private houses or carriages are yet a novelty, and those who possess them have something which few of their neighbours can show. For this a few people are no doubt prepared to pay, as they are, or were, for blue china, or a first edition uncut, with wide margins. Statements as to the cost of electric lighting on a small scale are therefore of little consequence in such cases as these, but it is questionable whether the progress of electric lighting may not be somewhat hindered by unqualified estimates of the cost of lighting an incandescent lamp by a primary battery, or at all events by any battery yet in the market. People will be induced to have a room or rooms fitted up with lamps, and will purchase batteries to supply their current. Soon afterwards, when the novelty has worn off a little, the cost will be measured, and then comparisons, which are proverbially odious, will be made. The gas will be again turned on, and the electric light in general will acquire a reputation for costliness because of the cost of these cases in particular. It therefore seems desirable that the attention of the public not versed in technical differences should be called to the necessity for observing that electric lighting by primary batteries must, at least so long as zinc is the element consumed, remain enormously costly as compared with electric lighting by currents from dynamo machines.

To most of our readers anything that we may say on this subject is unnecessary, but the frequency with which primary batteries have been talked of lately in this connection, especially by our daily contemporaries, makes it desirable that sufficient should be said by us on the subject to prevent, if possible, the spread of any idea that the cost of electric lighting is to be measured by its cost with primary batteries. In one case in particular it has been freely published that the cost of the light has been brought down as low as one-eighth or 0·125 of a penny per hour for each five-candle lamp, this, of course, being pointed to as recommending the batteries. Even assuming this to be true as covering the whole cost of the current, the cost is very great for lighting on a large scale or for any length of time, though, as we have already said, there are numerous special applications wherein the cost is a matter of small moment. These cases, however, are but infinitesimal as compared with the demand for electric lights, when procurable at the present cost of gas, or only a little in excess of that. Frequent reference lately has been made to one battery having been shown to the public, but which in reality has not been shown at all. It has been applied to a railway carriage, and much has been made of it. The cost of the lighting by it is given in as above, and it should be noted particularly that it is not per ordinary 16 or 20 candle lamp. It is admitted that the oxidising element in this battery is zinc, but the nature of the electrolyte is not stated, and other details are at present withheld. That zinc is used, however, is sufficient to tell us the cost, and to prevent mistakes it may be at once pointed out that this is at the least ten times the cost of the light when dynamo machines and engines are used.

Taking zinc as costing 3d. per lb., the cost for this metal alone per horse-power would be 6d. per hour, assuming the E.M.F. to be 1 volt. One horse-power will not give more than 200 candles in incandescent lamps. We therefore have as the cost of these batteries for zinc alone $\frac{6 \times 5}{200} = 0{\cdot}15$d., instead of 0·125d. as stated. On the other hand, the cost by steam engine would not be more than 0·015. Why so costly a system should be favoured for railway carriage lighting we cannot tell. It is certainly not our province to point out where gas has its special applications, but until satisfactory arrangements of dynamo machines and durable secondary batteries in brake vans can be made, the best lighting for railway carriages is undoubtedly the Pintsch compressed oil gas, for convenience, cheapness, and lighting power. The primary battery that shall oxidise iron or lead has not yet appeared, and until something of the kind does present itself it may be confidently said that railway carriages, or rooms, will not be cheaply lighted by primaries. We believe a form of lead primary is likely to be brought out ere long, and if this is the case the superiority of the incandescent electric light over all others will enforce its adoption in railway carriages and other places where a motor and generator are not admissible.

# CORRESPONDENCE.

## ENDLESS CHAIN DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Although I have not seen the Fonvielle *tourniquet* machine, from Dr. Ermacora's description of it I have no doubt that it rotates under the same influence as the passage of the iron rod in my experiment, the current cessations or reversals taking place in the coil more quickly than the changes of magnetic state which they induce in the continuous iron disc. It, however, requires alternating currents to produce continuous rotation.

In the case of alternate iron and brass links passing through a solenoid under the inductive influence of the current and *polarity* of the solenoid, the alternate change of magnetic state of the chain as a whole is analogous to the magnetic change produced by the reversals of current in the disc machine, the speed and the number of alternate links in the former having the same effect as the number of reversals of current in a given time in the latter.

In the Fonvielle machine a continuous rotary motion is produced by alternate currents acting on a continuous iron disc, whilst in the chain dynamo a continuous current acting on alternate iron and non-magnetic links produces the same result. In the former the inducing *cause* is alternating, in the latter the induced *effect* is alternating, inasmuch as an alternate iron and brass chain is only capable of *receiving* the magnetism at every alternate link.

Dr. Ermacora seems to be in some doubt about my experiment. I can only say that I have since had the opportunity of repeating it, and have no reason for thinking that any accidental action influenced the result.

Dr. Ermacora says "in passing through a solenoid an iron

Digitized by Google

core passes only through one maximum of magnetisation, which takes place a short time after crossing the central position, according to the retardation of magnetic action. The distribution of the lines of force in a solenoid puts the fact out of question." I do not think the matter is so easily disposed of. Dr. Ermacora evidently entirely ignores the polar inductive effect of the solenoid, and I discern that it is through this we differ, and as Dr. Ermacora cannot share my opinion as to the difference between permanent magnets and solenoids the accompanying diagrams may help to explain.

If a bar of soft iron be placed parallel to, but outside of a solenoid (Fig. 1), the N pole of the latter induces a S pole in

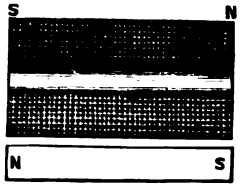

Fig. 1.

the bar, as shown. If, however, the bar is placed *in* the solenoid, the currents circulating in the latter cause the bar to be of the same polarity as itself; at the same time the N and S of the solenoid still tend to induce the same polarity in the bar as when the latter was outside of the former, and this, it will be seen, is of opposite sign to that which it would acquire when placed in the interior of the solenoid. When the bar is in the solenoid, its polarity, caused by the current, overpowers the inductive effect of the polarity of the solenoid. The latter inductive action nevertheless occurs, and weakens the magnetism produced by the current; in other words, an electro-magnet would be more powerful if the solenoid did not develop polarity, supposing it still to retain its power of rendering an iron bar magnetic in its interior.

This double induction may be, perhaps, better understood by referring to Fig. 2. Two soft iron bars, I, are placed in a

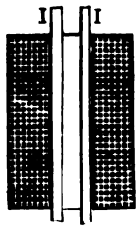

Fig. 2.

solenoid. As would be expected, as soon as magnetised, they separate and fix themselves to the opposite sides of the internal diameter of the solenoid. There are two forces set up in this case, (1) a repelling force between the two bars by reason of their being magnetised both of the same sign, (2) the attraction to and caused by the interior of the solenoid. The *apparent* polar state of the iron bars is of the same sign as the solenoid, but inasmuch as they are attracted to the latter such attraction could not occur without their having magnetism induced in them of opposite sign to the solenoid. The bars, therefore, are subject to *two opposite inducing causes or induced effects.*

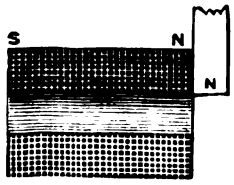

Fig 3.

I do not think it is possible, with any arrangement of permanent magnets, to produce similar induction on a soft iron bar.

The inductive action of the solenoid pole plays an important part in the experiment which puzzles Dr. Ermacora, so much so that by bringing an auxiliary pole of the same sign to the end of the solenoid, as in Fig. 3, the effect is increased.

The illustrated experiment in my last letter would certainly produce alternate currents. The circuit could be broken, however, each time the rod passed out of the solenoid, thereby utilising one current only, that caused on its entering the solenoid. This would constitute a series of electrical waves all in the same direction, and would practically be a continuous current. The amount of power developed is simply a matter of construction. In attempting to explain the theory—which Dr. Ermacora thinks is very simple—that gentleman says "each iron rod in crossing the solenoid acts as conductor of the lines of magnetic force which go from one pole to the other of the permanent magnet. At each passage of an iron link a concentration of the lines of force in the solenoid takes place; after the passage of the iron link such an effect disappears. So that if there are not *coils cutting lines of force*, there are lines of force cutting the coil." I hope to prove that the current generated in this manner does *not* depend on cutting lines of force. In fact, if it were possible by an effort of the imagination to instantaneously transform the air contained in the solenoid into solid iron I should expect the same result as would be obtained by mechanically inserting an iron core.

When the core is in the solenoid, as seen at Fig. 4, it

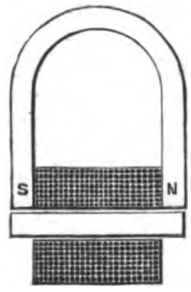

Fig. 4.

forms, practically, a closed magnetic ring. It is known that in a closed magnetic ring, however powerful the *internal* lines of force may be, no, or extremely little, outward magnetic effects can be detected, and consequently no apparent polarity. Such being the case, how can the currents produced in this manner be caused by coils intersecting lines of force that in reality do not exist *outwardly*, they being concentrated *in* the iron core?

I take this mode of electrical generation to be analogous to the increase of current caused by inserting an iron core in

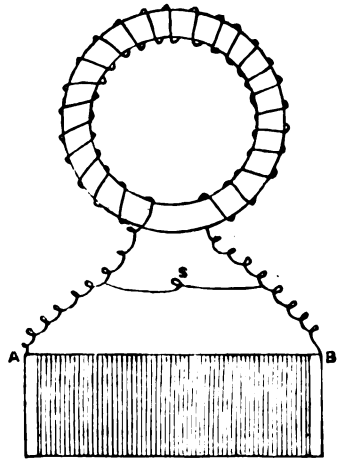

Fig. 5.

a solenoid with a make and break arrangement. The currents produced in an induction coil do not depend on *outward* lines of force at all, inasmuch as the most powerful current that may be obtained by this method of induction can be

Digitized by Google

taken from a coil in which the soft iron core does not develop the slightest apparent polarity. Let Fig. 5 represent a soft iron ring coiled as a continuous helix. A and B are battery terminals. S is a shunt conductor of high resistance. When A and B are closed the ring is powerfully magnetised, although no *outward* polarity can be traced if it is carefully wound. On breaking contact at B the ring is demagnetised, and the current so produced may be caught in the shunt conductor S.

This being a direct current causes it to be more powerful, because each convolution acts as inducer and induced on its neighbouring convolutions.

There can be no doubt that the current in this case is caused by the ring being deprived of its internal magnetism, so that breaking contact in this case is analogous to drawing out the iron rod at Fig. 4.

If Dr. Ermacora has any more to say on this subject, I should be glad if he would give a rough sketch of Page and Breguet's machines, or say where they can be seen.

The whole of magneto-electrical phenomena are so interwoven that it is difficult to strictly define a discovery, but at present I am under the impression that the mechanical generation of electricity in the above manner is decidedly new.—Yours, &c., E. L. Voice.

London, November 24th, 1883.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Referring to Mr. Farquhar's criticism of your correspondent "W. M. H.'s" letter of the 17th Nov., is he not aware that if a piece of iron be placed across the poles of a magnet there will be very little external field? Now this is exactly the case in point. In the case of the Edison machine I should advise Mr. Farquhar to take an early opportunity of examining the bed plate, and perhaps he will find "some discontinuous (in a magnetic sense) arrangement" by no means "studiously concealed in each." It is rather startling to find the Brush dynamo quoted as an analogous case, where, as far as magnetic action is concerned, the bed plate is a matter of perfect indifference, since the points connected by the bed plate are at the same magnetic potential.

I hope Mr. Farquhar will take warning and amend his design, otherwise I fear there may be another "defective dynamo."—Yours, &c., A. B.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am afraid Mr. W. T. Farquhar has misunderstood my answer to Mr. Oldham's question. In the first place, the pole pieces of a dynamo are the pieces which form the poles of the magnet, and between which the armature revolves. Neither in the Edison, Brush, nor in any other machinery are these pieces joined to an iron bed-plate. Of course the legs of the field magnet are joined by an iron plate at the top, or there would be no magnetic continuity.—Yours, &c.,

Claremont House, Lee. W. Hitchcock.

## SECONDARY GENERATORS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: On reading the description of the lighting of Edgware-road and other stations on the Metropolitan Railway by the National Company for the Distribution of Electricity by Secondary Generators, in your last issue, it struck me that the term secondary generators is a misnomer. As I understand the matter, these so-called generators do not in reality generate anything; they merely convert one kind of current into another. They seem, in fact, to be a series of induction coils, the wires of which are all taken to one commutator, from which the circuits are led.

I am considerably puzzled also as to the efficiency of these induction coils, but suppose we must wait patiently until tests have been made.—Yours, &c.,

London, Nov. 26, 1883. Enquirer.

## TOO WORDY.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In these days, when brevity is not only acknowledged to be the "soul of wit," but also of many, if not most other things, why should electrical companies adopt such outrageously long titles? Take, for instance, "The Anglo-American Brush Electric Light Corporation (Limited)," and "The National Company for the Distribution of Electricity by Secondary Generators." Is there not room for a little reform here?—Yours, &c., Brevity.

## SEISMIC DISTURBANCES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I was not aware that the "silly season," so afflicting to newspapers in general, could possibly have any influence on a subject so essentially serious as that of earthquakes; yet "A. H.," in his letter to the *Echo*—indicated by your correspondendent of the National Telephone Company—without apparently any grounds for his assumption, quietly informs the world that *somewhere* another big earthquake is about to take place.

Nor does your correspondent show any proofs of originality, seeing that on various occasions your columns have been opened to similar matter, collected where "earthquakes do dwell," and which, I think, will be generally admitted as more plausible and possible than the theory he expounds. In order that he may disabuse himself of the erroneous idea that "electricians do not trouble (?) themselves with seismic questions" (as if an electrician knew what *trouble* was!) your correspondent may refer to your back numbers, and learn that, on the contrary, we do very much trouble ourselves on the subject.

Various are the theories which from time to time have been suggested as causing earthquakes, but daily and hourly it becomes more certain that all others must give way to the only practical one of magnetism. Let it be clearly understood, however, that there are earthquakes *and* earthquakes. I cannot accept the assertion that the recent subsidence in Ischia or the upheavals in Java belong to the seismic class, as generally understood.

I am aware that many of your readers anxiously expected to hear what "Earthquake Forster" had to say on the subject of the recent outbreaks, but in point of fact I repudiate them as members of our family. To anybody who has resided in Naples and its neighbourhood it must have been palpable how peculiarly unstable and flimsy the whole place is. Vesuvius, but a few miles off, has drawn and still draws into its vitals, and has belched forth its contents for many centuries past, the whole of the undercrust of the surrounding country. Take the opposite side of the gulf, go to Agnano, the Solfatara, Pozzuoli, and Bajea, all places in the immediate vicinity of Ischia. Here with your stick you may turn up the boiling earth, cross ground as hollow as an empty barrel, or trace the filtration of mineral water, which by its continuous erosion undermines the supports of *those immense caverns formed all around by Vesuvius's rapacious hunger*, and the day comes when the "last straw" causes a collapse. Go into Naples itself, up to Capo-di-Monti, to the royal palace, and there the heavy footfall re-echoes back the hollow sound of the void beneath you, and tells you but too plainly what will, what *must*, be the fate of the city at your feet. As Ischia fell so must Naples fall, for the phenomena of the one are common to the other. Nobody who heard that fearful "rombo," as of immense masses being detached from the bowels of the earth and dragged to the vortex, in the streets of Naples during the great eruption of Vesuvius in 1872, can ever efface from his mind the impression that the city is doomed.

There is not a shadow of doubt that the catastrophe of Ischia was entirely due to the same cause, and the fact is proved by the actual results.

The movement was purely superficial, and it is from near the surface that Vesuvius draws its sustenance, it is near the surface that mineral waters filtrate the most, otherwise the immense power would have been equally felt over the whole

Digitized by Google

island and severely in the neighbourhood, whereas, in point of fact, it was almost unfelt in the town of Ischia, four miles away.

Actual seismatic force has its basis much farther off, and the radius of its angle, if I may use the term, must necessarily cover a wider area than any subsidence of the earth possibly can. There must be a limit to the drain of a volcano on the earth's deposit, and when this is reached it is simply a question of time for the crust to topple over, and until Vesuvius's activity is silenced for ever Ischia and all around must submit to its dictates.

The "transformation scene" at Java is so purely volcanic that it bears no possible relation to earthquakes in their accepted term, and appertains rather to the geologist than to the electrician. I would simply mention a fact which seems to have been overlooked, viz., in 1881 the subsidence at Ischia was followed twenty-seven days after by that of Chio, that of Ischia in 1883 was followed twenty-seven days after by the Java "smash up," and both those of Chio and Java were equally and proportionally more disastrous than their precursors. Was this a simple coincidence?

That the shocks of earthquake which almost daily occur in Japan, and are very frequent in Southern Europe and Asia Minor, are due to other than volcanic causes or to filtration is beyond doubt, and it is reasonable to suppose that by the aid of the large metallic surface offered by cables laying in earthquake centres we shall eventually be able to trace and localise their origin.

In a former paper I mentioned how the Japanese suspend a magnet with a weight something less heavy than its maximum of support over a metal basin, and the change in polarity, weakness or loss of magnetism, shortly previous to a shock, causes the weight to detach itself, and thus warn the people.

I had conducted my experiments on this basis, and with the successful results already known to you. That earthquakes may be predicted before they take place by carefully taking magnetic observations is undoubted, but there is a decided limit to such a period, and it is simply absurd to say that, because Ischia and Java have been "moved," we are to expect a third, unless, like the Greeks, our friend insists that accidents happen by threes, and that the same feeling which prompts the Greek to inflict upon himself a third personal injury after having met with two must necessarily apply to everything in nature.

It is rather an open question whether it is or not advisable to predict these shocks. I have certainly done so in three recent instances at a maximum distance of sixteen hours previously, but my friends object to being advised beforehand. They prefer, like myself, to know what are the noticeable effects at the time.

The affinity between earth currents and earthquake currents is very close, but whilst an earth current remains constantly positive or negative during one single observation, your earthquake current goes steadily backwards and forwards each side of your mirror-scale, and is strong or weak in proportion to the force of the shock.

Your correspondent will find that, if he really is in an earthquake centre, it *is not* his battery which is affected, but his galvanometer.

After a violent shock of earthquake my astatic galvanometer invariably is *hors de service* until the surrounding magnetic disturbance of the earth ceases, and it is most interesting to me to see my calculations thus confirmed.

The barometer *is* affected by these shocks, the thermometer not.

As I have previously informed you, although my experience of seismic disturbances extends over ten years, I have only recently had my network of cables brought into my immediate neighbourhood; hence my actual results are comparatively *nil*. Still, the earthquake period is approaching, and we may reasonably hope for a "continuance of past favours."—Yours, &c., W. G. Forster.

Zante, October 2, 1883.

[It will be seen that this letter has been in our hands some time, but the fact that various daily papers were at the time recording earthquakes led us to withhold for a time its publication. We now insert it as a contribution to "earthquake" literature, and to show, as Mr. Forster says, that thinkers and investigators are not wanting in regions where earthquakes abound.—Ed. *E.*]

---

Gravet's Rule.—*Errata.*—In Mr. Wm. Farrar's letter on this subject, published in our last issue, the following corrections should be made:—In the first column of page 39, last line, for "series" read "sines," and in line 5 of next column, for "lines" read "sines."

---

## THE INTERNATIONAL ELECTRICAL EXHIBITION AT VIENNA.

(from our special correspondent.)

X.

We have noticed most of the machines, although we have not yet given details of the exhibits of Ganz, Crompton, and others, and most of the incandescent lamps, so now we may speak of the arc lamps. Visitors entering the interiors from the hall behind the British pavilion would at first see interiors lighted by incandescent lamps; the last room of all, however, opening into the machinery annexe, was lighted by an arc lamp. This room, as was the next to it, was arranged as a picture and sculpture gallery, and enabled a good idea to be obtained of the value of this means of lighting. Unfortunately, the gallery that should have been lighted by the arc lamps was frequently not so lighted, but when there was light the contrast between the light of lower intensity from the incandescent lamps and that of the higher intensity of the arc lamps was very effective. The incandescent lamps used were those of Edison, so arranged that reflected and diffused light played their parts to give effectiveness to the scene. The general opinion was in favour of the whiter arc light for the purpose of illuminating such galleries. The arc lamps used were those known as the Sun lamps—a lamp which has been exhibited more or less in England, and has been often described. Some improvements have, however, been made, though the main idea is still the same. A brief description of this lamp will suffice. The inventor obtains a large radiating surface by raising a piece of refractory material, generally marble, to a high temperature, by means of an electric arc. The marble for a 1,000-candle lamp is 2 by $1\frac{1}{2}$ by $1\frac{1}{4}$in., and has one face scooped out like the mouth-piece of a telephone. Fig. 1 shows such a block with the

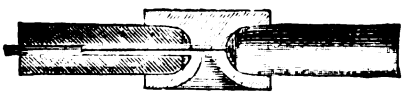

Fig. 1.—Carbons and Marble as used in the Sun Lamp.

hollow underneath. The ends of the marble block are drilled out to admit the carbons, as shown. These cylindrical holes differ, of course, in diameter with the carbon it is intended to use. A smaller hole is drilled through the marble, and one of the carbons used is hollow. The length of this small hole determines the length of the arc, which is found to be about 5mm. longer than the hole, because the ends of the carbon burn flat. In order to make the arc, a slender carbon rod is passed through the hole in the hollow carbon, through the hole in the marble, and into contact with the solid carbon. This contact-making piece can be withdrawn, and so the arc is made. Generally the contact piece is withdrawn by means of an electro-magnet, with the core of which it is connected. Fig. 2 shows the framework of a lamp. Fig. 3 shows the globe in which

Digitized by Google

the lamp is placed. A cut out is used, as shown in Fig. 4. In this the core of a solenoid carries two arms dropping into mercury cups. When a current passes through the coils the core with its arms is raised and the circuit through the mercury broken; if the current fails, the core falls and contact is made through the mercury. It will be seen that this lamp is more suited to run with an alternate than with a direct current, as with the former both carbons can be replaced at the same time, while, with the latter, care would have to be taken to have one carbon longer than the other, or to replace the carbons at different times. The carbons are kept close to the end of the cavity in the marble by the pressure of a spring, and the whole of a stick of carbon can be burnt. They burn more slowly than in ordinary arc lamps, for they are burning in a partial vacuum. We are inclined to agree with the opinion that has more than once been expressed, that this lamp belongs to the hybrid class, partly incandescent and partly arc.

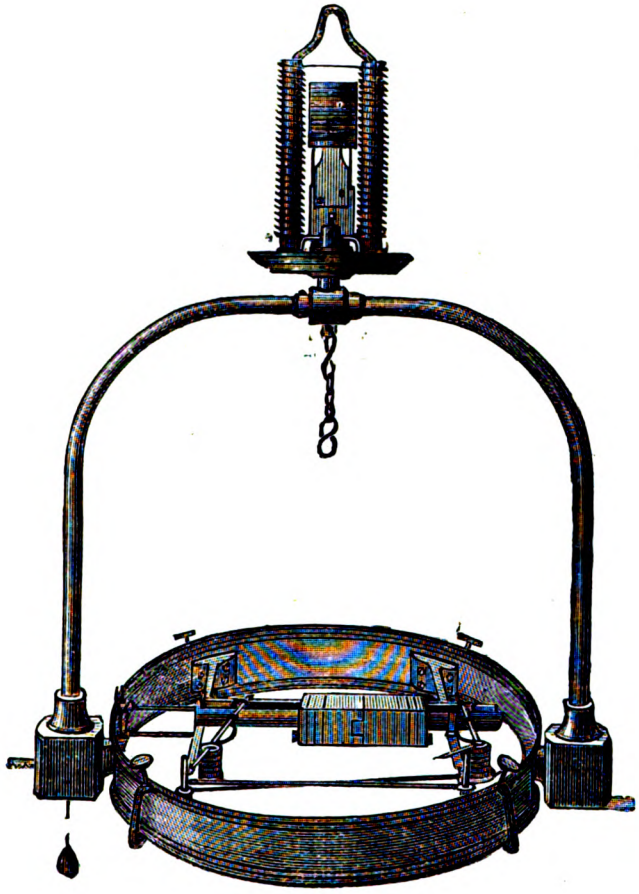

FIG. 2.—Framework and Details of Sun Lamp.

The marble becomes more or less a conductor, and hence is heated because of the current it conducts, as well as by means of the arc. The marble lasts from a few hours to fifty hours, according to the strength of the current, and the cost of carbons and marble is about the same.

It is difficult to feel satisfied as to the economy of this lamp. It may pertain to the luxurious—give a soft, steady light, but exact figures as to its cost from disinterested quarters are not forthcoming. If the lamp does belong to the hybrid class, as above mentioned, it can hardly be economical, for this class of lamp has hitherto been anything but satisfactory when the question under consideration has been cost. The Sun lamp appears to us to be rather a mistaken modification of the Jablochkoff. In the latter, as is well known, we have two parallel and vertical carbons separated by a material which dissipates as the carbons burn, but which serves to keep the carbon points a fixed distance apart. In the former we have two horizontal, or nearly horizontal, carbons, the points of which are kept at a fixed distance asunder by the use of a more refractory material than that used in the Jablochkoff. This refractory material is

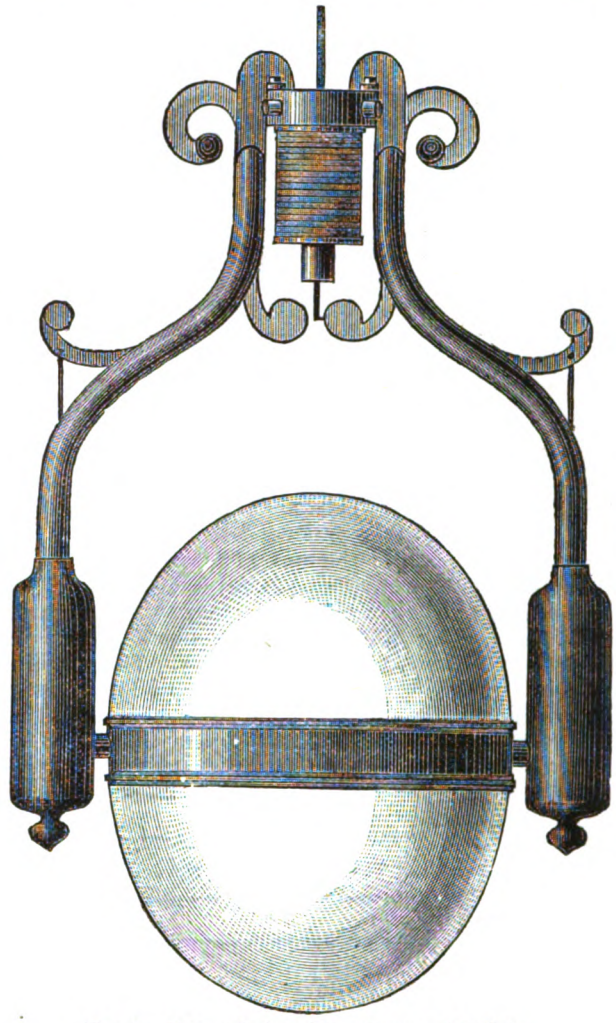

FIG. 3.—External view of Sun Lamp, with Globe.

increased in size, and is supposed to add considerably to the effectiveness of the lamp. Time alone will show the value of this improvement.

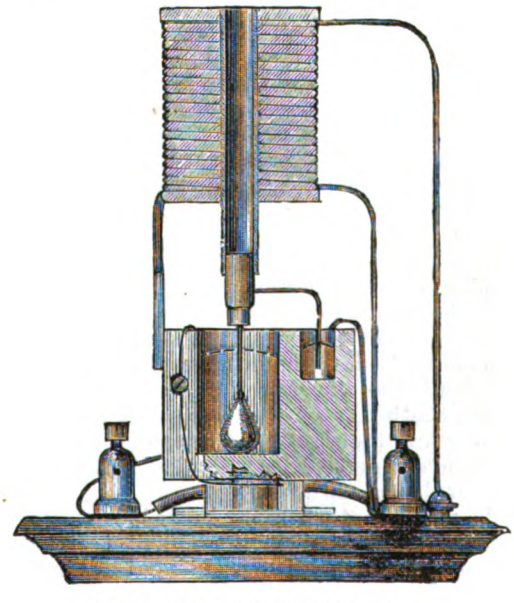

FIG. 4.—Cut-out used with Sun Lamp.

Before mentioning the other arc lamps a few words may be said about carbons.

It is in the carbons that most improvements tending to

Digitized by Google

economy and quiet comfort have recently been made, but other improvements may be looked for. Tests were long since made at the works of Sautter and Lemonnier as to the value of plating carbons with the following results :—

| Carbons. | Diam. | Length consumed per hour in mm. + | — | Total. |
|---|---|---|---|---|
| Naked | 7 mm | 166 | 68 | 234 |
| Copper plated | „ | 146 | 40 | 186 |
| Nickel plated | „ | 106 | 38 | 144 |
| Naked | 9 mm | 104 | 50 | 154 |
| Copper plated | „ | 98 | 34 | 132 |
| Nickel plated | „ | 68 | 36 | 104 |

The lessened consumption per hour is very noticeable.

## SUBMARINE MINES.

(CONTINUED FROM PAGE 35.)

*The Farmer Machine.*—This apparatus possesses decided advantages over any other thus far described; not only from the fact that it permits the use of low-tension fuses, but also because it acts by a very powerful wave of electricity of low potential, which has little tendency to escape through leaks in the leading wires, but yet has sufficient power to explode many charges arranged in series. The machine is encased in a strong box, 13in. by 11in. by 18in. in size, the whole weighing 120lb. It acts upon the double circuit principle, and is used in combination with a peculiar switch separate from the instrument. It consists essentially of a large soft cast-iron, wire-wrapped magnet, a Siemens armature with a suitably geared crank, and the switch. The armature is 6·5in. long, and 2·1in. in diameter, wrapped with copper wire of No. 19 B.W.G. It is geared to revolve about 7·3 times for every turn of the crank, which enables a strong man to give about 1,000 revolutions per minute. The magnets are wrapped with copper wire of No. 14 B.W.G.

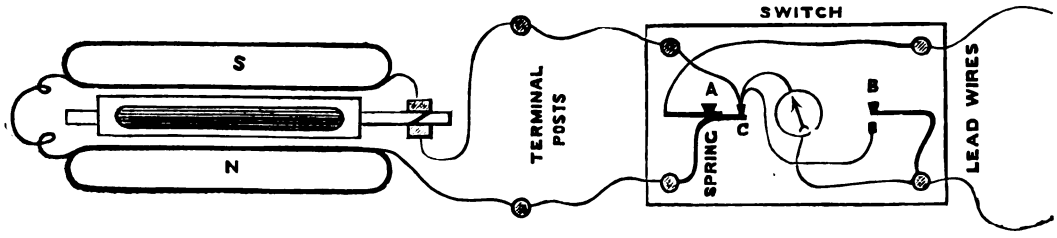

FIG 7.—Farmer Machine.

The circuit (see Fig. 7) is peculiar. Starting at one of the terminal posts, the wire passes round the magnets to one spring of the commutator, thence through the armature to the other spring, and from that to the other terminal post. Unless, therefore, these external terminals be connected no circuit exists. The switch, when attached, completes this circuit; and a rapid revolution of the crank calls for very great strength. By depressing the left-hand key the short circuit is broken, and the current is sent through the fuse and galvanometer back to the instrument. The resistance of the latter, about 100 ohms, protects the former from explosion, and the continuity of the circuit can thus be verified. By depressing first the right-hand key and then the left-hand key the galvanometer resistance is eliminated from the exterior circuit, and explosion ensues.

It will be noted that when the latter key is depressed the current sent through the exterior circuit is reinforced by the extra current developed by suddenly breaking the short circuit, and that a great increase of power is thus secured. Also, that this wave is momentary in character, since the exterior resistance reduces the strength of the current, and hence the magnetism rapidly diminishes. The explosion occurs, however, before this change has time to develop itself.

Perhaps no class of igniting apparatus is more difficult to subject to exact measurement than that to which this instrument belongs. The current is first employed to charge the field magnets to saturation, and then is suddenly switched through the fuse circuit, which in general has a resistance sufficient to immediately lower the magnetic intensity of the field of force, and hence to rapidly reduce the electromotive force. On the other hand, this *quasi* breaking of the circuit develops an extra current which for an instant largely increases this element. Notwithstanding this complex change the current does not cease, and hence the method employed with the Breguet apparatus [the equation given on p. 426 *ante*] is not applicable, because the ratio of the times of action certainly cannot be assumed to be unity. In other words, the electromotive force, and hence the strength of the current for successive differentials of time, first increases to an unknown degree, and then falls away at a rate which is a function of the external resistance.

Two methods of trial suggested themselves. The first was the same so successfully applied to the Gramme machine; but several causes of uncertainty and inaccuracy could not be eliminated, viz.:—(1) The exterior circuit employed (3·26 ohms) might or might not be too great to permit a normal development of the intensity of the field of force magnets. (2) The augmentation of the electromotive force due to the extra current would certainly be wanting. (3) The difficulty with all Siemens armatures, namely, that the current is pulsating even when turned by the commutator into a single direction, would render the electromotive force as measured by Law's method variable; indeed, that element must differ for every position of the contract terminals of the commutator. The changes in electromotive force are so rapid as hardly to influence the deflection of the heavy needle of the Gaugain galvanometer; but the instantaneous discharge of the condenser measures a particular value, and not the mean value which regulates the former. Nevertheless, to obtain some approximate results the method was tested.

The internal resistance of the machine being 3·13 ohms, a constant external resistance of 3·26 ohms was selected, and the crank was turned as rapidly as possible by a powerful and well trained man. The switch, of course, was omitted. The following table exhibits the results obtained :—

OBSERVATIONS WITH THE FARMER MACHINE.

| No. of Experiment. | Observed. T. | Observed. E′ | Measured C By Gaugain. | Measured C $\frac{E'}{3·26}$ | Measured E. By Gaugain $(3·13+3·26)C$ | Measured E. By Law's method $\frac{3·13+3·26}{3·26}\times E'$ |
|---|---|---|---|---|---|---|
| | | volts. | weber. | weber. | volts. | volts. |
| 1 | 924 | 5·70 | 3·13 | 1·75 | 20·00 | 11·11 |
| 2 | 1·020 | 14·60 | 3·13 | 4·48 | 20·00 | 28·47 |
| 3 | 1·056 | 6·64 | 3·24 | 2·04 | 20·70 | 12·95 |
| 4 | 1·020 | 7·20 | 3·35 | 2·21 | 21·41 | 14·04 |
| Mean | | | 3·21 | 2·62 | 20·53 | 16·64 |

When the exterior circuit was reduced to ·14 ohm, 1,000 revolutions of the armature per minute gave a current of 6·40 webers, corresponding to 6·4 (3·13 + ·14) = 20·93 volts.

Digitized by Google

From this it would appear that the most serious cause of error in this method of measurement is due to *the failure to develop the extra current*, which must considerably raise the electromotive force available for firing a fuse.

The second method for determining this quantity, devised in 1876, consisted in placing a box of resistance coils and a low-tension fuse, which required a current of ·5 weber for ignition, in the exterior circuit, sending the wave as usual through this circuit, but at first unplugging enough resistance to prevent ignition, and reducing this amount ohm by ohm until the fuse was fired. This plan rendered it easy to compute from Ohm's law the effective value of E by multiplying the amount last unplugged plus the resistance of the fuse and leading wires (·87 ohm) plus the internal resistance (3·13 ohms) by ·5. The following experiments were made in this manner:—

| | | ohms. | | volts. |
|---|---|---|---|---|
| Experiment 1 ... | Last amount unplugged, | 60 ; | E.M.F., | 32 |
| Experiment 2 ... | „ „ | 52 ; | „ | 28 |
| Experiment 3 ... | „ „ | 54 ; | „ | 29 |
| Experiment 4 ... | „ „ | 60 ; | „ | 32 |
| Experiment 5 ... | „ „ | 55 ; | „ | 30 |
| Experiment 6 ... | „ „ | 60 ; | „ | 32 |
| Experiment 7 ... | „ „ | 55 ; | „ | 30 |
| Experiment 8 ... | „ „ | 54 ; | „ | 29 |
| Experiment 9 ... | „ „ | 65 ; | „ | 34 |
| Experiment 10 ... | „ „ | 55 ; | „ | 30 |
| Mean ..... | | | | 30 |

Since these results, reached by methods so different, accord so well, it would appear that the full working power of the machine when used to generate a wave, as in igniting low-tension fuses, may be represented without material error by the following formula:

$$C = \frac{30}{3{\cdot}13 + R'}$$

That is, the internal resistance being 3·13 ohms, the machine with 1,000 revolutions per minute will develop for an instant an effective electromotive force of 30 volts; although not more than 20 volts can be continuously obtained at that speed. The former value is sufficient to explode, near the instrument, about twenty carefully selected service platinum fuses connected in series; double that number have occasionally been fired at a higher speed. After such a statement it is quite unnecessary to add that the Farmer machine is admirably suited for river or sea service. Indeed, it has been adopted in the United States Navy for the latter purpose. One secret of its power lies in the fact that the armature revolves in unusually close proximity to the poles of the magnet. To this fact, and to the judicious winding and the utilisation of the extra current, its great power is due.

Like all machines containing a commutator, there is a certain liability that a short circuit may be made between the opposite pieces by metallic dust caused by wear, and also that the contact of the springs may become defective. In case of failure these points should be first examined.

*The Smith Machine.*—This instrument is identical in theory and construction with the Farmer; but it contains an ingenious device for dispensing with the external key, which in blasting is troublesome to a man who for economy is also trying to turn the crank. It is essential to a good development of the power that the short circuit shall be broken when the armature is revolving at full speed. The latter requires vigorous exertion; and the operator is likely to involuntarily slacken his efforts in trying to manipulate the key, thus causing a possible failure if many fuses are in circuit.

Smith obviates this objection to Farmer's machine by providing a short circuit between the terminals within the case. Part of this circuit consists of a movable arm belonging to an arrangement resembling a gun lock at full cock. The trigger is worked by a small armature placed near the soft iron magnet, and is so adjusted as to require the full power of this magnet. When this is developed the trigger snaps, and the mainspring acting on the movable arm suddenly breaks the short circuit, thus shunting an electrical wave through the external circuit. By this device the firing is automatic, and the operator has only to turn the crank, being sure that so soon as he has attained a sufficient speed to develop the full power, the wave will be sent through the fuse. The trigger is reset mechanically by the next revolution of the crank. Smith's machine is encased in a strong box 13 by 10 by 15in. high, the whole weighing 77 pounds. The magnet and armature are wound with copper wire. The former of No. 13, and the latter of No. 16 B.W.G. The total internal resistance is ·56 ohm. The gearing of the crank gives six revolutions of the armature to each turn of the handle.

To determine the electromotive force generated by the machine, and hence its effective equation for the work for which it is designed, the method by fuses described for the Farmer machine was adopted. About 1,044 revolutions of the armature per minute, the practical limit for which the trigger is set, were given. The internal resistance of the machine being ·56 ohm, of the fuse at explosion ·9 ohm, and of the leading wires ·19 ohm, the constant resistance was 1·6 ohm. Adding the maximum amount in ohms which could be unplugged without preventing explosion, and multiplying the sum by ·5 weber, gave the following values for E:—

| | | | volts. |
|---|---|---|---|
| Experiment 1 ..... | 20 ohms unplugged ; | effective E, | 10·8 |
| Experiment 2 ..... | 20 „ „ ; | effective E, | 10·8 |
| Experiment 3 ..... | 20 „ „ ; | effective E, | 10·8 |
| Experiment 4 ..... | 23 „ „ ; | effective E, | 12·3 |
| Experiment 5 ..... | 25 „ „ ; | effective E, | 13·3 |
| Experiment 6 ..... | 20 „ „ ; | effective E, | 10·8 |
| Experiment 7 ..... | 20 „ „ ; | effective E, | 10·8 |

Hence for the fuse firing equation of this machine

$$C = \frac{12}{{\cdot}56 + R''}.$$

This equation indicates that eight service low-tension fuses, coupled in series on short circuit, can be fired with certainty, and experiment confirms the prediction. With a considerably larger number failures are rare. A single fuse can be fired through an external resistance of about 20 ohms. For military purposes Smith's apparatus is decidedly inferior to the Farmer machine, because the instant of firing is not so perfectly under control, but for ordinary blasting it evidently possesses merit.

(TO BE CONTINUED.)

## SOUTH AFRICAN BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

Lieut.-Col. GEORGE COXON, the chairman of this Company, presided at the first annual meeting of the shareholders, held at the Cannon-street Hotel last Monday afternoon.

The Secretary (Mr. THOMAS J. SEEL) read the notice convening the meeting.

In moving the adoption of the report and statement of accounts, the chairman said certain explanations were necessary with regard to their expenditure and revenue, as shareholders had written asking how it was that the directors had spent £10,000 in making £5,000, and in one case the writer announced that, failing a satisfactory explanation, he should move the winding up of the Company [hear, hear]. They could take no objection to that, or to the other letters, which were only such as could be expected under the circumstances. But first taking the item in the profit and loss account of £5,202 received for services of lights, for a period from 15th May, 1882, when the Company was formed, until 30th June, 1883, it must not be supposed that the Company was in receipt of revenue all that time, or that this sum really represented the actual revenue at this moment. The revenue might now be taken at about £10,000 a year. Nor did the £10,945 in the same account shown as expended during the same period represent the rate of expenditure by the Company at the present time. This item of expenditure included a very large amount of preliminary expenses, such as for travelling, and exhibiting the lights at Port Elizabeth, which could never occur again. The great bulk of the expenditure was embraced within the early part of the fourteen months, whereas for only

Digitized by Google

four months in one instance, and two months in another—referring to their contracts—had the Company derived the full benefit of the income arising from the expenditure. The Company started on the 15th May, 1882, when the expenses commenced for salaries of existing staff and London expenses £4,300 a year. During August four additional staff were engaged, two of whom turned out to be exceedingly expensive and worse than useless. Travelling expenses amounted to £767, advertising to £182; and the exhibition of the light at Port Elizabeth, £308. Altogether £1,258 was incurred, for the most part at the commencement of operations, whereas for similar services in future a comparatively insignificant sum would suffice. [A Shareholder: How much?] It was impossible to state; he should think from £200 to £300 a year. As to the receipts, the sixteen lights at Kimberley were begun three and a half months after the starting of the Company. That was when they got to paid work, but then for six months they ran those lights at a loss. On the 1st March the thirty-two lights were started, so that for the whole period over which the accounts were made up they only had the thirty-two lights. Therefore it did not require very close reasoning to see that a heavy loss must of necessity have been incurred on the contract up to that time. At Cape Town the Company had only had the benefit of their contract with the dock authorities for two months, because when it was originally taken they were obliged to hire fuel and motive power, for which they had to pay exceedingly high prices. In April they commenced with their own engine, and were making a fair profit as far as they could at present see. It was apparent that no other result than that obtained could be expected from the first year's trading, but now they came to two very important points—what were they doing now, and what did they recommend in the future [hear, hear]? As to the first, their gross revenue from existing engagements was £9,879 per annum, and their expenditure was, as nearly as could be calculated from data in their possession, only such as could be covered by the receipts. At present they looked for no profit, but they would be on the safe side. Their manager at the Cape (Captain Dunlop) held very sanguine views, but the directors did not take them into account; they simply judged as well as they could from the past as to what they might be able to do in the future, and when they said the revenue would cover their expenses, they believed they were saying what was perfectly a fact. The directors were careful not to mislead the shareholders; their expenditure might be a trifle more, and there might be a trifling loss. The fact was that, unexpectedly, expenses cropped up here and there for the moment that existed no longer in the next month, or were very much reduced. To mention a single instance, fuel—that had gone up enormously of late at Kimberley because of drought, but this had passed away with the heavy rains. They were covering their expenses under heavy disadvantages in a respect still more serious. It was a time of most unexampled commercial depression. They might therefore at the present time claim to be fairly holding their own, and that too without taking into account the very sanguine views entertained by their manager on the spot. The value and success of the lights had been freely acknowledged, and the question of their universal adoption throughout the Cape was simply one of cost—a question which unfortunately for them grew with the growth of the Company; and it was not too much to say that had the state of commercial prosperity at the Cape continued as it was when they started, the Company would have proved a very successful undertaking. Nor should they be justified in setting aside the probability of a return to that state of things as a factor in deciding their future course. He considered it a very important factor. It was important, too, to bear in mind that on the completion of the railway to Kimberley, which the Government was vigorously prosecuting, and he believed expected to complete as far as the Orange River by March next, the cost of coal would be very much reduced at Kimberley. It had been as high as £24 a ton, but there was no doubt the completion of the railway would reduce it to from £6 to £7. The expenditure under this head during the period stated had been £1,949. Far from the light waning in popularity, their manager had constant applications for it both in Kimberley and Cape Town, chiefly for the incandescent light, but these were for the most part of too isolated and scattered a nature to pay, even with the staff and motive power already available, unless they could be taken within the area of a further extension of the established arc circuits, and the directors had already given their reasons in the report for declining fresh contracts on a large scale, such as that asked for at East London. Having placed them in possession of the facts explanatory of the report and of the present position of the Company, they came to the very important question of the future, and what course the directors recommended for adoption [hear, hear]. This had had their most serious consideration. If they could see their way by the sale of concessions, plant, and machinery, and with the cash in hand, to distribute a substantial amount amongst the shareholders, it might, in view of the uncertainty of the future, be the better course [hear, hear]. But in the present position of business at the Cape this was absolutely out of the question. The only possible chance of a satisfactory solution in this direction was in holding on, so long as they could do so without serious loss, for better times, and with the certainty that, if better times came, an improvement, and an enhanced value of their property would come with them, without taking into account the improvement of the light. Should they wind the Company up now? [hear, hear]. Should they sacrifice the whole of the capital embarked in the undertaking, with all their chances for the future and at a time when, as it were, they were for the first time feeling their legs, and offer a distribution of about £5,000, or 5s. per share? ["No, No"]. The directors did not recommend this course, which he had only gone into because he knew it had been freely mooted amongst the shareholders from a natural ignorance of the real position of the Company. But what they did recommend was that they should reduce the shares to £3 each, leaving a liability only of 10s. instead of £2 10s., which he was informed was by no means a costly operation, and that the Company should continue their work on the lines the directors had endeavoured to indicate, at all events for the present and until such time as they might think it prudent in the interests of the shareholders, according as events transpired for good or not, to call them together again. This might be done at any time—in three, six, or nine months, and they might depend upon it, should their interests demand it, the directors would not defer the time a single day. Reverting to the motion for the adoption of the report, the chairman concluded by expressing his desire to place on record on behalf of himself and the directors their high sense of the invaluable services rendered by the secretary (Mr. T. J. Seel), whose perseverance and ability had succeeded in evolving the succinct statement of accounts from the most appalling chaos.

Mr. PORTER RHODES having seconded the motion for the adoption of the report,

Mr. EDWARD CLARK said the chairman had made the best of a sorry business, and his explanation had been satisfactory to such an extent that he should abandon his intention of moving that the Company should be wound up at the present time. He thought the most prudent course to be recommended to the meeting was to write down the shares at once to £2 10s., the existing liability being a serious thing for many. The Company had £7,000 in hand, and there was no reason why there should be kept over the shareholders *in terrorem* the remainder of their liability. He should move that the shares should be reduced accordingly.

Mr. THOMAS offered to second the proposition.

Mr. T. DICKSON (one of the directors) said that with regard to the ten shillings a share upon which Mr. Clark differed with the chairman, it might happen that the Company would get into a good flow of business. Again, the Cape might improve in its trade. If a little more money should then be wanted it would be exceedingly unsatisfactory to have to go to a lot of legal expenses in order to obtain it. If the directors said there should be no further calls without the sanction of the shareholders, the matter remained in their own hands, with power to take advantage of the ten shillings per share should the opportunity arise.

The CHAIRMAN ruled that as he had received no notice of Mr. Clark's intention to move a reduction of the share capital, his proposal could not be put at that meeting.

Mr. CLARK: I think if you take advantage of me in that manner it will not be courteous to the shareholders. I sent you notice of my intention to move for the winding up of the Company. That I withdraw.

The CHAIRMAN: You cannot move the other; it requires a special notice.

Mr. CLARK: Why, then, did you give such serious weight to my letter?

The CHAIRMAN: Your letter was mentioned with others in proof that it was necessary for the directors to make an explanation. By your own admission you were not in possession of information which we had the pleasure of giving.

In further reply to another shareholder, the CHAIRMAN stated that the directors considered an allowance of 5 per cent. for depreciation of machinery, plant, and construction was more than sufficient considering the short time during which the machinery had been in use.

Mr. J. C. HOWE, who stated he had just returned from South Africa, expressed the opinion that not 5 or 15 or 20 per cent. was sufficient to write off for the depreciation of the machinery. It might only be worth the freight to bring back again, and three-fourths of the machinery, especially of the diamond mining machinery, was the same. As for the light in Kimberley, it was depreciating every day, and the accounts of the Company would show that they had to allow the Kimberley Corporation a certain amount for insufficient lighting and defects in the lighting. There was not the slightest chance of the Kimberley contract being renewed, and he could speak authoritatively on that point, because he had conversed with nearly every member of the corporation. Considering it was really that contract alone that had contributed to the payment of any large portion of the working expenses, it was nonsense for business men to carry on the Company [hear, hear]. The Corporation of East London would have nothing to say to the light.

The CHAIRMAN declared that this was a statement that demanded correction for, as the report stated, proposals had been made by the Town Council of East London and declined. Judging Mr. Howe's statements by the light of this one they could scarcely carry much weight. It was an extraordinary thing for a gentleman to assert that because diamond machinery had depreciated, therefore dynamos were equally worthless. He presumed the speaker had confused the two [laughter]. As for the Kimberley Corporation, the less said about its members the better. Their conduct had been such as would not bear ventilation with regard to the Company, who had a fair and honourable contract with them, and stood on one side of the line whilst the corporation stood on the other. He would not say what that line was. The corporation had taken every means, fair or foul, to act against the Company; attempting to deprive them of the income of a light for twenty-four hours' use because it went out for one, and having spies in their pay to spy out every little defect. No honest man could bring a single atom of proof that the lights of the Company had not been a success in Kimberley. Failures had occurred in other places. Even in the city of London the lights all went out in a night. Mr. Atkinson, a member of the Board, was at the Cape now, and although he had not been to Kimberley, the lights were as good there as at Cape Town which he had seen. The directors were told these were better than at Eastbourne, which were supposed to be superior to any on the south coast.

Mr. HOWE declined to defend the Kimberley Corporation, but he emphasised the fact that there was no chance of the renewal of the greater portion of their income. In East London they had no contract, nor was there likely to be one in Port Elizabeth.

The CHAIRMAN added that the fact was the Kimberley Corporation had made abatements to the Company which the directors had not accepted. The payments received from them had been accepted without prejudice, and the directors had taken counsel's opinion, which would guide them very distinctly.

Replying to the Rev. H. T. Johnson, the SECRETARY stated that although the bulk of £3,043 due from sundry debtors was included in the amount of £5,202 for services of lights in the profit and loss account, most of it had been paid since making up the accounts, only about £500 remaining still due.

Mr. JOHNSON was convinced that the expenses in future would be very little short of what they had been, and as no margin was left for carrying on at a profit, the shareholders must conclude, as the directors had hitherto been too sanguine, that instead of being able to pay their way the Company would again lose. As to when their property should be realised, it could not be contended that the Brush system was the system for the future, and his opinion was that the plant should be disposed of at the best possible price, the salaried officers discharged at once, and the Company wound up. About £10,000 would then remain, which would give 10s. a share.

The CHAIRMAN replied that this estimate was founded on their position six months ago. The staff could not be summarily discharged, because

Digitized by Google

the agreements with them, and he could conceive nothing more fatal than liquidating now. Besides, the Kimberley contract did not terminate until August 24, 1884. As to its renewal, the Company might then have a different set of men to deal with. The corporation did not hold office in perpetuity, and the inhabitants of Kimberley and the town council were of different classes. Would the merchants and the gentlemen of Kimberley consent to forego the light, having had it for three years? In answer to Captain Stewart, he added that the Company would have to pay for getting out of the contract if they wished to do so now, and it would be no mere matter of form.

Mr. SHARP moved the adjournment of the meeting in order further to consider the position.

This was seconded by Mr. CLARK.

After some further discussion of an irregular character, the CHAIRMAN put the original motion to the meeting, and declared that the report and statement of accounts had been adopted.

Mr. SHARP protested against his motion for adjournment being ignored as it had been.

Messrs. Deloitte, Dever, Griffiths, and Co. were re-elected auditors, and the proceedings terminated, the chairman giving an undertaking that the shareholders should be called together at the soonest possible moment—within a month—in order to discuss the reduction of their liability.

## THE SOUTH-EASTERN BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

The first ordinary general meeting of the shareholders in this Company was held at the City Terminus Hotel, Cannon-street, on Tuesday, under the presidency of Sir Michael Kennedy.

The SECRETARY (Mr. Alfred Jermyn) read the notice convening the meeting. The directors' report and balance-sheet were taken as read.

The CHAIRMAN: Gentlemen, our report gives you very full information upon the present position of the Company's affairs. We drew it at greater length than is usual in such cases because we desired that you should have an opportunity of forming a judgment upon our past proceedings and our present prospects before we met you here this day. The balance-sheet is not so satisfactory as some of you no doubt expected, and as we all could wish, but we have had great difficulties to contend with, which have beset all electric lighting companies. But I think we can honestly say that we have done better than most. I need hardly remind you of the sanguine expectations that we entertained in regard to the immediate prospects of electric lighting when this and other companies were launched in the spring of last year. But, gentlemen, this is a new industry, and it requires time and careful organisation for its successful development. It cannot be expected to be the growth of a day or of an hour. In gas, water, railways and tramways, and such like undertakings, capital must be expended and revenue cultivated before profitable results can be attained, and if it be so in such well-known and old industries, it, *à fortiori*, must be the case in a new industry which is still in its infancy, but of which it is hardly now possible to forecast the future dimensions. The main difficulty that met us at the outset was the want of legal powers, and a system complete in all its parts. Again, as we have told you in our report, we have now obtained in our provisional orders an extended field of operations in eight of our principal towns, and in the B.K.T. we have a system complete in all its parts or all its *minutiæ* from the motor to the lamps. When we started we had only our Brush patent to depend upon, and these, although admirable for arc lighting, did not give us what we needed for incandescent lighting, which was most in demand. We had not even a secondary battery, nor I believe at that time had anybody else, and without storage we found that incandescent lighting upon a large scale and upon the continuous supply system was impracticable. We have now a secondary battery which I believe is inferior to none, and with it we can use our admirable Brush machine, and indeed any other machine, with the greatest advantage. I say any other machine, gentlemen, and I beg that you will mark my words, because I now tell you that negotiations which had not been concluded at the date of our report have since been brought to a successful termination, and we have arranged with the Brush Corporation that we are free to use any system that we may think fit. We found that being tied to one system operated greatly against us in procuring our provisional orders, and was likely to operate still more against us in working those orders. We brought that to the notice of the Brush Corporation, and they met us in a very fair and friendly spirit, and the result has been an arrangement, the heads of which I will now read to you. Having read the heads of the agreement, the chairman continued: I think, gentlemen, that you will agree with me that this is a very fair and equitable solution of the difficulty under which we are labouring. By it we are free to use any system that we may find most applicable, and the Brush Corporation cannot come into our district to compete with us without paying us a liberal royalty upon all the sales they may effect, or the business they may do. We had hoped by the time of this meeting to be able to tell you that our installation at Colchester had been completed, but it has been delayed from various causes, and it will be still some weeks before it is running on the B. K. T. system. But all the street work has been finished, and cables laid for the installation of 2,000 lamps, the probable ultimate demand being from 5,000 to 6,000 lamps. The accumulators, with all the necessary apparatus, are in rapid course of manufacture, and the first delivery of this apparatus will take place at Colchester within a few days. The total cost of this installation has been estimated upon very careful data at about £10,000, and upon equally careful data the net profit that will be derived from it has been estimated at over 12 per cent., and as the number of lamps increases this profit should increase at a higher rate. But it is not alone, gentlemen, from the direct profit that this installation will produce that it is valuable to us. It will be the first installation of town lighting on a large scale under the Electric Lighting Act in this country, and we cannot doubt that the success which we anticipate from it will lead to a very large extension of our business, and enable us to carry out the rest of our provisional orders to great advantage. We look forward to this installation to bring us a large acquisition of business directly, and also indirectly, from the demand that it will give rise to for the apparatus and machinery manufactured by the Consolidated Company, in which we have so large an interest. You will see on both sides of the balance-sheet an item of £20,000, being the nominal value of 20,000 shares that this Company holds in the Consolidated Company. The real value of these shares will, of course, depend upon the success of the Consolidated Company's manufacturing operations, and upon the mode in which they will deal with their patents. As far as we can see there is every reason, amounting to a certainty almost, that the profit on these manufacturing operations will amount to at least 5 per cent. upon the total cost of the capital of the Company, and probably to a great deal more. Looking only to the main article of manufacture—the accumulator cells—and disregarding the profit which will undoubtedly be made upon other apparatus, such as volt meters, cuts-out, switches, and such like, the rate at which the factory is now prepared to turn out, and is actually turning out, if carried on throughout the year, will insure a nett profit of at least £5,000, and from the number of orders placed, we anticipate, and have the best reason for anticipating, that the factory will not be able to comply with the demands which will be made upon it, and it will have to be very much enlarged. A very good judge upon the subject has said that if the Consolidated Company's accumulator will do what it professes to do, and what we believe there is no doubt that it will be able to do, then the demand for it will be practically unlimited, and there will be room not only for our present factory, or an enlarged factory, but for any number of factories; and there need be no selfish rivalry between companies engaged in the same class of business, for there will be room for all. As regards the patents, the Consolidated Company is now in negotiation for the sale of their French and Spanish patents, and judging from the results that have been obtained elsewhere there is every prospect of this class of business being very profitable to that Company. I see it stated in a scientific journal which is usually well informed, "that by an arrangement just concluded in Paris, on behalf of the French Metropolitan General Electric Company (Limited), the sum of £30,000, to be increased in certain eventualities to £75,000 before the end of the year, is payable to the Electrical Power Storage Company (Limited) for their interest in the Faure accumulator patents for France, and in commutation of all royalties. The latter company has also, it appears, sold the right to use the Faure-Sellon-Volckmar accumulators for the whole of Germany to the Edison Company of Berlin for a considerable sum—over £50,000 in cash, and heavy royalties during the currency of the patents, besides a participation in all the subsidiary companies to be formed." We think, gentlemen, that our, or rather the Consolidated Company's secondary battery, is at least as good as that of any other company. We anticipate that we shall have our fair share in any arrangement such as I have just been reading to you, and I think it is encouraging at all events to learn that a company which bears the name of Edison is prepared now to give so heavy a price for a secondary battery. The Consolidated Company's factory has begun to do good business after an expenditure of £8,000. This includes the cost of patents, of plant, of machinery, of stock, and the working expenses up to the present time. If so trifling an outlay was able to bring this factory up to the producing point, I think it compares very favourably with what we hear as to the outlay that has had to be incurred to bring other concerns doing similar business up to the same point. Such, gentlemen, is briefly the outline of our present outlook, and I trust it will appear to you, as it certainly does to your directors, to be full of promise. If you believe, gentlemen, that there is anything in electric lighting, and that there is any foundation whatever for the movement, then I think you may anticipate a success for this Company, which will reward us for all the troubles and difficulties that we have had in the initiation of the business. If you do not believe it, it is another matter. But if the great and growing opinions of most thinking men in all countries, and the fact of an increased and increasing demand for it be any guide, then I think there is an enormous field for this industry, and if there be, as the proprietors of this Company, you are in the very front of the movement [applause]. Gentlemen, I beg to move "That the report and balance-sheet now presented be, and they are hereby, approved and adopted."

Mr. FRANCIS FESSER (deputy-chairman): Gentlemen, in rising to second the motion just made by our chairman, I wish to go more particularly into the accounts. You will find in the profit and loss account that our working expenses during the year, that is to say from the formation of the Company, which is rather more than a year since, to the 30th June last, were £3,981 3s. 5d. Now the question naturally arises, what work has been done for the money? I say to any one who will take the trouble to inquire and make himself acquainted with the work that has been done, he will find that it is quite satisfactory. In the first place we have had to go into and canvass over the whole district. We have had to approach every local authority, every manufacturer, in fact almost every establishment from which we hoped to derive business. We had to acquire the statistics of every town, and, I may say, of almost every village in our district. We have had to satisfy ourselves by making inquiries as to the particular kind of light demanded, as to the necessities and the desires of our future customers, and also as to the method of supply which would be most likely to meet those desires. We became satisfied shortly after our labour commenced that the system of central stations or house to house lighting was the only one that would meet the requirements of the public, and that very few, not even manufacturers, could be induced to invest capital in generating their own electricity, not to speak of want of technical and scientific knowledge, which is so much felt by electrical companies, and much more by people who are ignorant of this entirely novel industry. As I say, we felt satisfied that the system of central stations and house to house supply was, in fact, the only one that was sure to give good results. In order to do this we had, under the Electric Light Bill passed last year, to obtain provisional orders. I believe very few gentlemen present, except those connected with electric light companies, are aware of the immense labour involved in procuring and preparing these provisional orders. We were going before the Board of Trade, and ultimately before Parliament, to seek legislation on an entirely new road. Nothing at all resembling it had ever been the subject of legislation in this or any other country, and therefore we had to bring to bear on this subject a number of most troublesome and wearisome negotiations and investigations, and take steps with the local authorities, with the Board of Trade, and with legal counsellors and with people provided with electrical and technical knowledge, and the result has been the formation of the provisional order which has been

Digitized by Google

generally adopted by the Board of Trade, and which is universally recognised as quite a monument in its line. That has given the directors—and, I may say, the whole staff of the Company, including the manager and the electricians—a very great deal of arduous labour. Next, finding ourselves unprovided with a complete system of incandescent lighting, as our chairman has said, there was the necessity of getting the means of furnishing it, and of securing the patents referred to, of examining them, of testing them, and finally all the study of the negotiations and the work which eventually culminated in the successful establishment of the Consolidated Company has been very arduous. Turning to the other side of the balance-sheet—to the profits—we find a total of £650 10s. 9d. represented by profit on sales, installations, hire and loan of instruments, interest, transfer fees. The amount is really larger. There have been some installations, for instance, productive of loss, and a loss that we willingly incurred (and I venture to say that we wisely incurred it), because it was necessary to make known the electric light [hear, hear] in many places in our district where it had never been seen before. It was necessary to bring it to the notice of the inhabitants, and these installations served as so many advertisements, which I dare say have been, or certainly will be, productive of a great deal more possibly to us than the slight loss incurred in them. So you must, therefore, look upon the business actually done as larger than what is represented by these figures. We have a profit of £650, as against a working expenditure of close upon £4,000. That is not, however, disheartening, for I do not think there is any industrial company in the world that would in the first year make profits to cover their expenses, and we can much less expect this in an industry so new and so little known as lighting by electricity. We must also reflect that our working expenses in the second year will not be necessarily larger, though our business will I hope increase. Although we have been obliged to keep a certain staff to meet all the demands that might be made upon us, that staff will not necessarily be larger for three or four times the business we do. And I hope a great deal of the preliminary business in the way of investigation and gaining knowledge upon all the matters connected with this subject will fructify in the future.

A SHAREHOLDER said that, being himself connected with a company similarly engaged, he knew the great difficulties that had to be met in a new undertaking like this, and he could therefore well imagine that the directors could not have made the progress they had done without incurring a very large amount of expenditure. But inasmuch as the directors, the managers, the whole of the staff in fact, and the offices were the same in this Company as in the Provincial Brush Electric Light and Power Company, he thought that they ought to be able to deal with both companies as one undertaking. Hence, while he would have eulogised the directors for the smallness of the expenditure if it had been connected with both undertakings, he must say it was far too heavy for one, and he would therefore suggest that the shareholders, in concert with the Board, ought to take in hand the consideration of an amalgamation or a working arrangement between the two companies [hear, hear]. It appeared to him that it would be a very fair thing, taking into consideration all the circumstances connected with the companies, that this should be done. This Company, for example, had paid a very moderate sum for its concession—some £10,000, whereas the other company had paid nearly £50,000 for its concession, and this Company had only £1 10s. per share called up, while the other had £2 10s., so that, balancing the two things, he thought it would be an equitable arrangement if both companies were to share alike and effect this amalgamation or working arrangement. This would not only save the time of the shareholders, because only one meeting would be necessary for both, duplicate circulars would not have to be sent out, and the enormous expenditure for printing and other charges would be thus reduced. If the directors would agree to this he was thoroughly with them in the general policy they were pursuing.

Mr. ETLINGER thought that the expenses were very moderate in getting the business into a state of development. There was one omission in the report—the result of the working to date was a loss of £5,596 12s. 4d., including the amount written off from the concession and preliminary expenses, £2,965; and as the accounts now stood that balance would have to be carried forward to the next half year, and would form the first item in the next half year's debit; so that if they were to earn £5,000 odd profits not a shilling would be available for dividend. They would be saddled with the total expenditure incurred in establishing the business, whereas he thought it ought to be spread over several years. It should therefore be carried to suspense account, to be dealt with hereafter, and he would be happy to move a resolution to that effect.

Mr. FRY begged to remind the gentleman who last spoke that he entirely forgot that, supposing between this and next year the Consolidated Company proved to be a success—which the Board expected it would be—they might still part with their 20,000 shares, some of them perhaps at £1 premium, and one should take credit for the value of those shares. The directors believed them to be worth what they stated them to be worth, and therefore he did not think it was an objectionable way of stating the accounts, but on the contrary a very fair way of putting them.

The auditor expressed his opinion that the course adopted in the balance-sheet was by no means an unusual one. The adoption of the accounts as they stood did not imply that they carried forward that balance as a direct charge for the next year, but one simply to be dealt with in the future.

Mr. C. J. LEE wished to know how the assumption in the first paragraph on the third page of the report went, beginning "Assuming a supply of only 2,000 incandescent lamps burning 1,200 hours per annum at the rate of 6d. per unit, or ½d. per lamp of 20 candle-power per hour," &c., because if they assumed certain things and ignored other things, they could not estimate what the profit would be. He would like to know also what was the state of the arrangements made with regard to forming local companies referred to in the report, and whether any were in course of formation. The expenses seemed to be rather heavy, but, considering the difficulties that lay in the way of engineers and others through want of experience, there was not much to grumble at. It was a new industry, and they did not yet know how to go to work in the most economical manner. He heartily approved the suggestion for the amalgamation of the two companies. As the directors were partners in these concerns it seemed to him that they ought to "draw it as mild" as they possibly could in the matter of fees while the shareholders were on the wrong side of the hedge, and after they earned profits they would be prepared to vote to them a handsome remuneration for their services.

Mr. E. BROOKES thought that the names of the directors and officers of the Company should be printed on the report and balance-sheet, and suggested that the directors should not receive fees until profits were earned.

The CHAIRMAN, in reply to Mr. Lee's question in reference to the local companies, said that negotiations were in progress in several quarters, but it was not advisable in the interests of the Company to enter into details on this occasion. They were moving as fast as they could in that direction. As the shareholders seemed inclined to give the Board their confidence as regarded past proceedings he hoped they would continue to do so in reference to this important matter, and not hamper them with any unnecessary questions. Putting aside the question of directors' fees, he thought the expenses of the whole establishment were very reasonable, and even if the two companies were formed into one they could not be reduced any more. As to the directors themselves, he did not think it fair, considering the great amount of work they had had to go through in connection with the management and development of this new concern, that the shareholders should expect them to do that work for nothing, any more than they should expect their manager, secretary, or clerks to give their services gratuitously.

The MANAGER (Mr. George Offor) reminded the meeting that the deputy-chairman had been in Madrid and Paris, personally negotiating the sale of the patents belonging to the Consolidated Company without charging a farthing to the Company towards defraying his travelling expenses or anything else, a circumstance which he thought ought to satisfy every shareholder (even Mr. Brookes) that the directors were not only working hard in the interests of the Company, but were not overpaid for the services that they were giving to them. With regard to the paragraph referred to by Mr. Lee, the estimates were based upon their actual experience obtained at Colchester. There, as the shareholders were aware, they had completed their plant of 2,000 lamps, so far as the street works were concerned, and their lighting station with one engine (a duplicate engine would have to be supplied when the whole number of lamps had been put upon the circuit), and they had ascertained this, that with an installation of 2,000 lamps only, at the rate at which the Colchester people were willing to take the light, that was 6d. per unit, or ½d. per lamp per hour—taking the cost of the plant, and debiting that cost with 10 per cent. written off for depreciation of plant, and 5 per cent. interest on the capital employed, the revenue derived from 2,000 lamps only would give them a net profit of £12 14s. 4d. per cent. Consequently there was no actual assumption in order to arrive at the profit. As the chairman pointed out the district over which they had laid their cables would ultimately require 5,000 to 6,000 lamps, and their profits would increase as the number of lamps they put on from their central station increased.

Mr. LEE wished to know whether the report was absolutely complete—whether, for example, there were any directors going out of office.

The CHAIRMAN: None.

Admiral INGLEFIELD regarded the preliminary expenses as very moderate. The success of any company must depend on good management, and if they got men of position and experience to sit at the board of such a company as this the shareholders must be prepared to pay them. He thought that their storage battery which he had taken the trouble to examine was the best he had ever seen. Would the chairman be good enough to state to the meeting what the price of the secondary batteries was? And he would like also to know if they had the foreign patents available for sale.

The CHAIRMAN in reply said, that as far as they could determine at present, the selling price of their battery cells would be £2 10s. each, which was lower than that for the cells of other companies. As regarded foreign patents they possessed them in a great many countries—nearly everywhere. These patents were the property of the Company. In answer to another question put by a shareholder, the chairman said that it would no doubt be necessary by and by to make another call, because they had their provisional orders to take up, their deposits to be paid, and they had, as would be seen by the accounts, a considerable amount of expense incurred to meet; but he would say this, that the directors would not call up a large amount. With reference to the amalgamation of the two companies he did not think at present it was advisable to consent to the appointment of a committee to consider it, because after all it was only a one-sided affair. It was not known what the Provincial Company would have to say as to the movement. Personally he would be happy if a good arrangement of the kind could be carried out. It was no new idea to the Board, and if they could do it on an equitable basis, they would be prepared to go into the question, and give it their best consideration. He concluded by moving: "That the report and accounts now submitted, be, and they are hereby, approved and adopted, subject to a modification of the accounts by providing that the item of £5,596 12s. 4d. to the debit of profit and loss account be carried forward, to be dealt with hereafter."

Mr. FESSER again seconded the motion as thus amended, and it was carried with one dissentient (Mr. Brookes).

Messrs. Price, Waterhouse and Co., were re-appointed auditors, and a vote of thanks having been accorded to the chairman, the proceedings closed.

## THE PROVINCIAL BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

The first ordinary general meeting of the shareholders of this Company was held at the City Terminus Hotel, Cannon-street, on Tuesday, under the presidency of Sir Michael Kennedy.

The SECRETARY (Mr. Alfred Jermyn) having read the notice calling the meeting, the directors' report and statement of accounts were taken as read.

The CHAIRMAN, in moving the adoption of the report, made a statement similar to that which he had made at the meeting of the South-Eastern Brush Electric Light Company, as above.

Mr. FRANCIS FESSER (deputy chairman) seconded the motion, and explained that the working expenses of the Company during the fifteen months of its existence had been £4,123 18s. 2d.—an amount which the

Digitized by Google

directors could not but think the shareholders would admit, in view of the work that had had to be accomplished, was not by any means excessive. For this expenditure they had, as in the case of the South-Eastern Company, explored the district in which they had undertaken under the terms of their prospectus to foster electric lighting. They had to collect statistics and knowledge of every kind in every town and village and every manufactory or other establishment where they were likely to be called upon to provide the light. That was a work of very considerable labour, entailing a great deal of expense; in fact, the same amount of labour and trouble had to be gone through as in the case of the South-Eastern Brush Electric Light Company, and he hoped the return for this outlay would be very large. They had laid the foundation of future operations, established their reputation, and gained knowledge as to the means of working which no doubt would in future be very profitable. Coming to the other side of the account, they would find that the gross profits amounted to £810 14s. 11d., which, however, did not represent the whole of the business done, because they had to make a number of experiments by way of advertising the system of lighting in towns that had not had an opportunity of seeing the light. This expense they did not hesitate to incur in view of what it was likely to bring to the Company afterwards in increased business. Although they did expect in a moment of very great excitement better results, still that was very good for a new industry during the first year of its existence. The directors flattered themselves they had now gone through the most difficult stage of the business, and that they were entering upon the pleasantest part of it. They only asked their shareholders to have a little patience, and see whether the expectations held forth were well grounded or not.

Mr. MARLHAM asked to what extent the Company was pledged to supply money to the Consolidated Company. Could not an independent expert be called in to make a report on the value of the work done in the factory for the satisfaction of the shareholders in the allied companies? How much money was there now in hand, and when this was exhausted what did the directors propose to do? Would they resist a petition to wind up the Company?

Mr. HALL thought that the directors and other officers' fees were enormous. He was sorry that the shareholders could not take the directors exactly into their confidence, because the directors had everything to gain and nothing to lose by going on with the Company. The sacrifice had been among the shareholders, a good many of whom would not think it a bad thing to wind up the Company. The number of directors might be reduced from seven to four, who might be each content with £100 till something was earned by the shareholders.

Mr. STEWART could not agree with the last speaker as to winding up the Company. He was of opinion that the foundations of a good business were laid, and having procured those provisional orders, and made a satisfactory arrangement with the Brush Company, whereby they were able to use other patents, he thought such a course would be most suicidal [hear, hear]. The proper thing to do was to unite this Company to the South-Eastern on equitable terms, and thus effect economies in their working.

Mr. BENNET asked that a special resolution might be passed calling a special meeting of the shareholders to say that the capital of the Company should be limited to the amount already paid up. It was a cruel thing to stand there with a bankrupt balance-sheet with the chance of paying £2 10s. more upon their shares while the directors sat at the Board and enjoyed all the advantage of a handsome remuneration.

After a few words from Admiral INGLEFIELD, recommending the shareholders to have confidence in the directors,

The CHAIRMAN, in reply to a shareholder, said that the holding of the directors was about 800 shares, which, as regarded the amount paid upon them, were the same as those of the other shareholders.

Mr. FRY (director) said that the shareholders might think that the Board had interests other than those of the proprietors, but they made a great mistake in that. The directors did not look to the extent of their pecuniary interest in the Company so much as to their reputation, which they had to consider. But the directors had embarked their means as much as the shareholders, because they believed this Company would be a success. As a Board, however, they were conducting the business on thoroughly commercial principles, and in that they looked for the support of the shareholders [applause].

Mr. R. CROWE wished the directors to pledge themselves to this, that they would make no call without taking the shareholders into their confidence.

In answer to a question addressed to him by a shareholder, Mr. FESSER said that they had still at the bank £7,000, showing that the money was not very soon spent.

A SHAREHOLDER asked whether the provisional orders would be carried out with the money now at the bank, and whether that would be enough.

The CHAIRMAN said that the directors had spent a large sum of money in making preparations for doing work, and in getting these provisional orders. Unless the shareholders put the Board in the position of having funds to carry out those orders the whole of that expenditure would be lost. That would be a most suicidal policy. As regarded the amount at the debit of profit and loss account (£6,800) they would be willing to meet them as they had done with the shareholders of the South-Eastern Company, and let it be dealt with hereafter. One gentleman asked what they were pledged to the Consolidated Company for? In answer to that he would say that the amount was £10,000, and they must bear in mind, whether the Company was wound up or not, it was liable for that amount. As to whether the directors would resist a motion for winding up, they most distinctly would, because they believed in the ultimate success of this undertaking.

The MANAGER (Mr. George Offor) then gave a brief account of what had been done by the South-Eastern Company at Colchester in carrying out the B. T. K. system of electrical distribution, and went on to say that, despite the feeling entertained by many that there was not a demand for electricity, wherever they went they found people anxious for the electric light. They were applied to right and left to go and supply the light, and the Consolidated Company with their system had been applied to by other companies and by local authorities to carry out the provisional orders which they had obtained. They would have as much business as it was in their power to do. His only fear was that they would not be able to compass it all.

After some further discussion, the following resolution, moved by Mr. W. H. ROBERTS, and seconded by Admiral INGLEFIELD, was adopted:—"That Admiral Inglefield, Messrs. Brodie, Braithwaite, Stewart, and Jervis be and they are hereby appointed a committee, with whom the directors express their desire to confer previous to making any call upon the shareholders."

The CHAIRMAN then moved the adoption of the report and accounts, subject to the modification of the latter by providing that the item of £6,824 6s. 6d. be carried forward to be dealt with hereafter.

Mr. FESSER seconded the motion, which was declared carried unanimously.

Messrs. Price, Waterhouse, and Co. were re-appointed auditors of the Company, and a vote of thanks having been passed to the chairman, the proceedings terminated.

## BRUSH MIDLAND ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

The second ordinary general meeting of this Company was held at the Terminus Hotel, Cannon-street, on Wednesday last, to transact the business of the ordinary meeting of the Company, in accordance with the Articles of Association, under the presidency of Mr. R. H. Glyn.

The SECRETARY (Mr. H. N. Myers) read the notice convening the meeting.

The CHAIRMAN: Gentlemen, this is our second ordinary meeting, and I only wish very much that the accounts which have been presented to you showed a profit instead of a loss. You will, I think, very fairly ask me how this loss has been arrived at, and you will also ask me to justify this expenditure. You will see that the total loss is £5,298. From that you can fairly deduct the legal expenses which we were put to in the Lane-Fox matter, which I will refer to later on. That matter cost us £1,500, and therefore our real loss has been about £3,700—that is for eighteen months' working. There is one very large item in these accounts—travelling expenses, &c. That item may be summed up in this way—salaries for eighteen months, £1,540; wages to the men who do our lighting, £623; and travelling expenses, £1,126. Now, the salaries seem large, but a business of this sort cannot be conducted by mere clerks, and we have to pay for people of some experience, not only in electricity, but in obtaining orders. The directors' fees—that seems a large amount. They are credited with £1,291—the full amount, but they have had only £606. The whole amount was put in by our auditors, it being a liability of the Company, and these fees have been calculated at the allowance of the Articles of Association—the full amount for one year, and half fees since. When we met last year and discussed the Lane-Fox question, we thought, although there was no particular value in the exclusive right to the Lane-Fox lamp, yet that we should get off cheaper. As a matter of fact, we have had to pay £1,500, our own costs and theirs too—that is what it amounts to. If you deduct these legal expenses, which are an unusual thing, and will not happen again, it leaves a loss, as I have said, of about £3,700. I do not know that there is anything else in the accounts to allude to specially. When we met you last year I stated that we would do all in our power to ascertain whether any one could be saddled with damages as to this mistake—or whatever they liked to call it—which was made in the prospectus, when we were supposed to have exclusive license of the Lane-Fox lamp. Well, the Board took eminent legal opinion upon the subject, and we were told that there was no one to blame. There are a considerable number of unpaid calls, amounting to £6,255. We have not pressed these gentlemen to pay up because we have had no means of employing the money. We are entitled to charge them under the Articles of Association a considerable amount of interest. I think as much as 10 per cent. Some of them are large shareholders, but the bulk are holders of ten or fifteen shares. What we are to do about the matter must be left, I take it, for further consideration. When we held our last meeting we had every prospect of a very good business. We had orders on hand which we were executing, and arrangements in progress in a number of towns in our district. We had expectations of forming local companies, not with a view of selling concessions at exorbitant prices, but for getting people in our district interested in our business, with the view of economy, for such business could then be conducted so much cheaper than from London. These, for the most part, fell through. I do not think it is very hard to tell the reason. The Lane-Fox business was pretty well ventilated, and that did not help us much. Then came the domestic squabbles with the parent Brush Company, which did not help that company much. Trade, too, has not been so good that people would go out of their way to change their present system of lighting for a new system. There is no question that the lighting of a factory means the outlay of money, and people do not want to lay out money unless they are making good profits. You see, at the beginning of this year we found ourselves practically in the position of having to decide whether we would give up the thing as a bad job altogether, or whether we would do our best to get orders, and the Board—not looking only at the shareholders generally, but to themselves, as probably among the largest shareholders of the Company—decided that it would not do to give the thing up, but rather that they should spend a sum of money in canvassing the Company's district, so that when the electric light comes to the fore again we might be able to make money out of it. I have no doubt you will think that was the right course to take. We were very much in the position of a tradesman who had got something which he believed in, but which the public would not take to at once. We believe certainly in the Brush system—I believe it is the best system. Well, this tradesman, would I think have been very foolish if he had said, "I will shut up, and will do nothing more. I have tried and failed, and though I know the thing is good, I will not spend any more money over it." That was precisely our position. We went to work, and I believe there is hardly anybody of any position in our district who has not had the advantage of the electric light explained to him. This is, so to say, an account of the past, and now with regard to the future. I have already said that we have so canvassed our district that there is no other company who is so well known—and I may say so favourably known—in our district as ours. We have put up certain installations. There have been occasionally little hitches, but I do not believe that we have a single installation going at the present moment which is not as near perfection

Digitized by Google

s any electric lighting is at the present time. We have made an arrangement with the Great Western Electric Light Company, which is favourable both to them and ourselves, whereby our officials are jointly employed and jointly paid. We have now before us the winter, which is the best time for electric lighting, and it seems to the directors that we should now try to get back something in the way of profit to recoup us for the loss we have as yet sustained. As far as I am personally concerned my impression is that the proper thing to do would be to have an amalgamation of the Brush companies. They could be managed so much more economically if there were only one company instead of the present large number. I shall be glad to answer any questions, but it is first my duty to move the adoption of the report and accounts.

Lord GREVILLE formally seconded the motion, which was carried unanimously without discussion, and the auditors (Messrs. Tribe, Clarke, and Co.) were subsequently re-appointed.

An extraordinary general meeting was then held "for the purpose of considering, and if approved, of passing a special resolution for the reduction of the capital of the Company from £250,000 to £70,500, the existing capital being in excess of the requirements of the Company, such reduction to be effected by cancelling 25,000 shares of £5 each, which have not been issued or agreed to be taken, and by reducing 21,800 shares, numbered from 1 to 21,800 inclusive, from £5 per share to £2 10s. per share," the other 3,200 shares belonging to the Anglo-American Company remaining unaltered, with £5 paid on each.

The CHAIRMAN: It will hardly be necessary for me to go into exact figures, but we had the power to issue a certain number of shares, and we are advised by our solicitor that this is the proper way to proceed in this matter. It appears that there are a large number of shareholders who wish that the liability of the shares should be limited to £2 10s. each. I cannot say that I see much in it myself, but there is no doubt that there is a feeling among a large number of the shareholders that this should be done. It has one advantage, perhaps, in that it limits the spending powers of the directors. If electric lighting should come out again I take it that we should have no very great difficulty in raising fresh capital if we wanted it. He then moved a resolution in accordance with the terms set out above.

Mr. JAMES PENDER seconded the motion, which was carried unanimously, and the meeting then separated.

## THE HAMMOND ELECTRIC LIGHT AND POWER SUPPLY COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on Monday at the Cannon-street Hotel for the purpose of passing and confirming the following resolution, authorising the issue of certain further deferred share capital on the amalgamation with Ferranti, Thompson, and Ince (Limited):—"That the directors of the Hammond Company be authorised to create and issue 16,000 deferred shares of the nominal value of £5 each, on the terms of the agreement already approved by the Hammond Company, and authorised to be entered into and carried into effect with the Ferranti Company."

Mr. PHILIP A. LATHAM (the secretary) read the notice convening the meeting.

Sir CHARLES YOUNG, who presided, said: We went fully into this matter at the last meeting, and I do not think I need go more into it now, and I will therefore propose the confirmation of this resolution (as above).

Mr. ROBERT HAMMOND: I have much pleasure in seconding that. I am glad to be able to say that in the interval between the two meetings, the Ferranti installation made by us at the First Avenue Hotel has been started, and gave on Thursday night, the evening of the opening of the hotel, immense satisfaction. One thousand lights are running from one machine there.

The CHAIRMAN put the motion, and it was carried unanimously, and the proceedings then terminated.

In the High Court of Justice, Chancery Division: Re the Duplex Electric Light, Power, and Storage Company (Limited).—Plant, Machinery, Stock, Office and Show Room Furniture, Fittings, and other effects.

MR. FRANK LEWIS (of Messrs. Frank Lewis and Co.), the person appointed by the Judge to whose Court the above cause is attached, will SELL by AUCTION, on the Premises, No. 9, SOHO-SQUARE, and 12, RATHBONE-PLACE, OXFORD-STREET, on MONDAY, December 10th, and three following days, at 12 o'clock precisely each day, the whole of the PLANT, Machinery, and Stock, comprising Voss and other electrical machines, Baudet's, Siemens', and Patrick's dynamos, air pumps, resistance coils, galvanometers, electric bells and gongs, App's and Rhumkorff induction coils, arc and duplex lamps, large quantity of brass electroliers of various patterns, porcelain shades and arc lamp globes, Morse instruments, electrical toys, large quantity of Bunsen's Smee's, Leclanché, and other cells, of all sizes, vacuum tubes, 1,500 flat porous pots, 7,000 glass bulbs, for incandescent lamps, 20 gross stoppered bottles, 3 cwt. glass tubing, 1 cwt. ebonite slips, 500 Siemens soft core carbons, brass work, including terminals, connectors, lamp top holders, &c., about 3 tons curled zincs and zinc cylinders for Bunsen cells, about 2 tons of lead sheets, 3 cwt. paraffin wax, quantity of bichromate, copperas, peroxide of lead, acids, and chemicals, about 3 miles No. 16 G.P. covered core, about 1½ ton wire double cotton covered, 8 20-gallon stone-ware acid pans, lead-lined cases, quantity of p.p. teak and beech for battery boxes, a nearly new 20 horse-power engine by Robey, fitted for electric lighting purposes, an 8 horse-power portable ditto, by Marshall and Son, of Gainsborough, a back geared screw cutting lathe, 6½in. centre, 7 other lathes, vertical drilling machine, shaping machine, large grind-stone, shafting and pulleys, hurricane forge, anvils, 20 vices, tools, 5 cwt. Pooley's weighing machine, carpenters' benches, &c., also the office, show room, and other furniture and fittings, consisting of mahogany writing tables, chairs, glazed show cases, marble top tables, partitioning and numerous other items. May be viewed the Friday and Saturday previous to sale, and catalogues had on the premises, of Messrs. Munns and Longden, Solicitors, 8, Old Jewry, E.C.; of S. Lovelock, Esq., the Official Liquidator, 19, Coleman-street, E.C.; and of Messrs. Frank Lewis and Co., Auctioneers, &c., 95, Gresham-street, E.C.

CIVIL SERVICE COMMISSION.—An OPEN COMPETITION for ASSISTANT EXAMINERSHIPS in the PATENT OFFICE will be HELD in LONDON, on WEDNESDAY, the 19th December, and following days. Preliminary examination in London on Saturday, the 15th December (age 21—25). Salary, £250 to £400. Forms of application may be obtained at once from the Secretary, Civil Service Commission, London, S.W.

NOTICE of REMOVAL.—Messieurs HASELTINE LAKE, and CO., Patent Agents, beg to announce that they have REMOVED to No. 45, SOUTHAMPTON BUILDINGS, CHANCERY LANE, opposite to their former premises.

TO ELECTRICAL ENGINEERS and those connected with Electric Light, Telegraph, and Telephone Companies.

A small premium will be paid by the Principal for each gentleman found a situation at a salary after passing through the year's course of PRACTICAL TRAINING at the Electrical Engineering College, West Worthing.

C. A. CARUS-WILSON, ELECTRICAL ENGINEER, 11, QUEEN VICTORIA-STREET, E.C., having had a large and varied experience in all branches of Electric Light Engineering, undertakes work for Local Authorities, Companies, or persons engaged in Electric Light operations. Complete specifications prepared, and every kind of installation work personally superintended and directed.

INSULATED ELECTRICAL WIRE, Silk, Cotton, or India-rubber covered. Conductivity guaranteed. German Silver Wires for Resistance. Braided Handle Cord, Silk Cord for Electric Bells, &c.—WILLIAM RICKARD, Derby London Agent (stock kept), EDWIN HOLLOWAY, 2, Gutter-lane, E.C.

## NOTES.

ELECTRIC LIGHTING IN THEATRES. — The Stuttgart Theatre has been lighted by the German Edison Company.

THE TELEPHONE IN AMERICA.—The Bell Telephone Company are, we read, building a new line between Boston and New York of No. 12 copper wire, which will be completed about January 1.

CABLE REPAIRED.—The Brazilian Submarine Telegraph Company's cable between St. Vincent and Pernambuco has been repaired, thereby restoring direct telegraphic communication with South America.

THE TELEPHONE IN ROME.—The *Société Italienne des Téléphones* have opened a central office in the Palais Sciarra at Rome. The king's residence, the Castel Porziano, is in communication with this exchange.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of November, 1883, amounted to £34,413, and to £32,591 for the corresponding period of 1882, being an increase of £1,822.

DEATH.—The death is announced of Mr. John Gibbs, chief of the technical department in the Belgian telegraph service, in which service he had for many years been employed. As his name would imply, he was of English origin.

ELECTRIC LIGHTING ON SHIPS.—The ss. "Vancouver," which is being built for the Dominion Line of steamers, will be lighted on the incandescent system by Messrs. Siemens Brothers. Swan lamps will be employed to the number of 300.

ELECTRICAL CONDUCTORS.—We notice that the discussion on Mr. Preece's paper on this subject, read before the Institution of Civil Engineers, on Tuesday last, was adjourned until next Monday. We give an abstract of the paper in another column.

NEW CABLES.—A Reuter's telegram from Athens, dated November 29, says that a convention providing for the laying of new telegraph cables between Greece and other countries has been signed by the Government and the Eastern Telegraph Company.

DIRECTOR-GENERAL OF TELEGRAPHS IN INDIA.—The tenure of the appointment of Director-General of Telegraphs has been limited to five years, and any extension of this term can be sanctioned by the Secretary of State alone. —*Colonies and India.*

UNDERGROUND WIRES IN PHILADELPHIA.—The Brush Electric Light Company has submitted to the assistant-superintendent of Police and Fire Alarm Telegraphs in Philadelphia specifications and plans for the laying of underground cables on Delaware-avenue.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended November 30 are £2,315, as compared with £1,128 in the corresponding period of 1882. The August receipts, estimated at £3,992, realised £4,060.

ELECTRIC LIGHTS FOR MINES.—At a meeting of the Royal Society of Victoria Mr. R. E. Joseph recommended the use of the electric light for mines, both for surface and underground work. He said it had proved successful at a Sandhurst mine, both economically and otherwise.

TELEPHONE COMPANY OF IRELAND.—This company announces the issue of 50,000 Five per Cent. Preference shares of £1 each, of which 30,000 are reserved to exchange for the existing Six per Cent. Preference shares, leaving a balance of 20,000 shares, which are now offered for subscription.

THE CALCUTTA EXHIBITION.—A Reuter's telegram from Calcutta, dated Dec. 5, says:—"The opening of the Calcutta Exhibition yesterday took place in the Museum. At the conclusion of the ceremony some person, who has not been discovered, cut off the electric light, leaving the assemblage in total darkness."

EARTHQUAKE SHOCKS AT SMYRNA.—Intelligence from Smyrna announces that two slight shocks of earthquake occurred there on Sunday last. A third shock was felt on Monday, and on Tuesday there was another and more severe one, accompanied by loud subterranean rumblings. No damage, however, has been done.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of November was 2,866, estimated to produce £2,550, against 2,005 messages, producing £1,842, in the corresponding month of last year. The traffic receipts for the month of August, estimated at £2,275, realised £2,315.

ELECTRIC LIGHTING IN FACTORIES.—Messrs. Woodward, Grosvenor, and Co. have adopted the electric light in their new carpet factory at Kidderminster. A Crompton dynamo and one hundred Swan lamps are employed, and the various work rooms are evenly and brilliantly lighted. The installation has been effected by Messrs. Holmes and Vaudry, of Liverpool.

LIGHTING OF THE SS. "ORLANDO."—With reference to the note on this subject in our last issue, Messrs. Oppermann Brothers write us as follows:—"The current was supplied by one of our low speed 100-light alternating machines, excited by a continuous current machine, both the machines being of our manufacture, and not only the smaller one, as would be understood from your notice."

A MINER'S SAFETY LAMP.—We would remind our readers that the time for sending in lamps in competition for Mr. Ellis Lever's premium of £500 is drawing near. According to the conditions issued in March last "the lamps must be sent to No. 2, Victoria-street, Westminster, London. No lamp to be sent in before the 1st of December, or none later than the 31st of December, 1883."

STEAMSHIP LIGHTING.—The City of Dublin Steam Packet Company, who have again received the contract for the mail service between Holyhead and Dublin, have decided to light their mail steamers by means of electric lights, and have entrusted Messrs. J. Edmundson and Co., of 19, Great George-street, Westminster, and of Dublin, with the work. This firm is now engaged in lighting the "Munster," which will be the first of the vessels lighted.

ACCIDENTS FROM LIGHTNING.—According to the colonial papers, tempestuous weather has been raging throughout New South Wales. The lightning struck a bank building at Taree, tearing away part of the roof, and causing the collapse of the ceiling. Three residents of the township were struck by the lightning, and considerably injured. Similar accidents occurred at other places, including Sydney. Within twenty-four hours over four inches of rain fell in Sydney.

ELECTRIC LIGHTING IN THE CITY.—The Streets Committee of the Commissioners of Sewers have resolved to recommend that the City be divided into five districts, comprehending the leading thoroughfares, for the purpose of electric lighting, and tenders are to be invited from various companies to carry out the work, which is to be done with as much promptitude as possible. This is in addition to one district for which a company has already permissive power.

Digitized by Google

THE MARSEILLES-ALGERIA CABLES.—The three submarine cables which unite France and Algeria are becoming insufficient, owing to the frequency of the telegraphic communications between Paris and the colony. To increase the capacity of these lines, the manager of the Marseilles office and an *employé*, M. Brahić, propose to transmit recorder signals by mechanism, adapted from the Wheatstone system, instead of by hand, as at present.—*L'Electricité.*

THE TRANSMISSION OF ENERGY.—The French papers state that fresh experiments are to be made on the transmission of energy between Paris and Creil on the Northern Railway Company's line. The experiments will be carried out by M. Deprez, and the expenses borne by the Rothschild firm, who it is rumoured may purchase M. Deprez's patents. Messrs. Rothschild have deputed three engineers to superintend the experiments on their behalf, and to report the result.

TO BE WOUND UP.—A petition for the winding up of the J. B. Rogers Electric Light and Power Company (Limited), was presented in the High Court of Chancery on the 3rd inst. It will be heard before Vice-Chancellor Sir James Bacon, at the Royal Courts of Justice, on the 15th inst.—The Electric Motor Syndicate (Limited), being satisfied that they cannot continue business, have agreed to wind up. Mr. A. Browne, of 5, Southampton-buildings, W.C., has been appointed liquidator.

SOCIETY OF TELEGRAPH ENGINEERS.—The annual general meeting of this society will be held on Thursday, 13th December, for the reception of the annual report and election of council and officers for the ensuing year. The following papers will be read:—1. "On an Instrument for Measuring the Strength of a Magnetic Field." 2. "On a Method of Calculating the Total Horse-power Expended in a Network of Conductors (such, for instance, as a system of street mains)." By J. E. H. Gordon, B.A., member.

THE WILLIAM SPOTTISWOODE MEMORIAL.—A meeting was to be held on Friday, at the rooms of the Royal Society, Burlington House, Piccadilly, when a proposal would be made for the appointment of a committee, and to make such other arrangements as might be considered necessary to the successful promotion of the memorial fund. Communications on the subject of the memorial may be addressed to Mr. J. S. Hodson, secretary of the Printers' Corporation, Gray's Inn-chambers, 20, High Holborn, W.C.

INCANDESCENT LIGHTS IN A SUGAR REFINERY.—The Edison Company of New York have installed 956 lamps in the sugar refinery of Messrs. Havemeyer and Elder, at Williamsburgh, New York State. The current is supplied by three K, one L, and one Z dynamo. The installation of these lamps required the placing of 25,000 feet of moulding, 425 feet of tubes for wire, and 3,200lbs. of copper wire. The dynamos are controlled by one automatic regulator, which regulates the electric pressure throughout the entire system.

ALTERATION OF A PATENT.—Notice has been given that Michael Radcliffe Ward has applied to the Commissioners of Patents for leave to file a disclaimer and memorandum of alteration of certain parts of the specification and title of his patent (No. 539, January 31, 1883) for "Improvements in or connected with tram, rail, and road cars, and other vehicles, and in machinery for driving the same by electricity." Any person intending to oppose such application must leave particulars in writing of their objections to such proposed disclaimer and memorandum of alteration with the Attorney-General's Clerk of the Patents, at Room No. 549, in the Royal Courts of Justice, London.

A MODIFIED LECLANCHE CELL.—M. Bleunard writes to *La Nature*, giving a description of a modification of the Leclanché cell which he was found cheap and useful. The plates consist of zinc and carbon, dipping in a saturated solution of bichromate of potash and sulphate of ammonia. With this arrangement there is no need to raise the plates out of the electrolyte when the cell is done with, as when the current is interrupted no action takes place in the cell. To prevent the creeping of the ammoniacal salts up the carbon, by which means the conducting wire is attacked and often broken, this plate is dipped into boiling paraffin oil. When cool, the superficial paraffin is scraped off, as that which penetrated the pores of the plate is sufficient to prevent the creeping.

AMERICAN TELEGRAPHS.—In his message to Congress, which was delivered this week, the President expresses himself as follows on the American telegraphic service:—"The President sees no reason to change the view expressed last year that the Government should not assume the same control over the telegraph as it exercises over the mail service. Admitting the authority of the Government, it would not, in his opinion, be a wise use thereof to purchase or assume the control of the existing lines, or to construct others for the purpose of competing with them. President Arthur, however, avows his belief that the Government should be authorised to exercise some sort of supervision over inter-State telegraphic communication, and hopes that a measure may be enacted with that object."

HOUSE LIGHTING.—The New York Edison Company have lighted the residence of Madame Cousino, at Santiago, Chili. The machinery is placed in a house built in the grounds specially for this purpose. It consists of a boiler by R. Wetherill and Co. of Chester, Penna, two Armington and Sims engines, four Z dynamos, &c. The current is conveyed to house, gardens, stables, greenhouse, &c., through more than 2,000 feet of underground conductors. There are 200 A or 16 candle-power, and 120 B or 8 candle-power lamps in circuit, which light every room in the house. The garden is lighted by lamps and reflectors placed on statuary, as well as by lamps introduced in the ornamental rockwork and fountains, while the four gate posts have each five lamps in a globe. The installation was carried out under the supervision of Mr. W. N. Stewart.

CARRIAGE LIGHTING.—The Consolidated Electric Company have recently constructed accumulators for the Provincial Brush Electric Light and Power Company which were used to light up Mr. A. de Rothschild's carriage on a test journey from Halton to Tring Station and back again on Sunday evening. The light is under the entire command of the occupant of the carriage, who can light or extinguish any of the lamps at pleasure. An incandescent light is placed in each of the ordinary outside carriage lamps, and one arranged with a small bracket and globe inside. The current is supplied from five cells containing six metal plates in each, which can be recharged without disturbing the arrangements by simply connecting two wires. The whole, being contained in a small mahogany case weighing a little over 1cwt., can be easily removed from the carriage if necessary.

FAILURE OF ELECTRIC LIGHTS.—A provincial contemporary, the *Derbyshire Times*, who, we may remark, seems to have a special and decided antipathy to electric lighting in general and the lights at Chesterfield in particular, gives the following account of a failure in the lighting of that town, which occurred some short time since:—"Another electric light failure occurred at Chesterfield on Sunday evening last,

Digitized by Google

when the important thoroughfare of West Bars was in utter darkness, owing to the sudden extinction of the incandescent electric light. Soon after the lights were turned on, they executed some very erratic movements, burning unsteadily, and dancing up and down in a most bewildering fashion, and finally they expired one after the other in rapid succession. Workmen were employed on the 'circuit,' but it was not till the small hours of the morning that the electricians succeeded in once more shedding their 'dim religious light' over the streets."

Luminous Jewels.—M. Gaston Trouvé, the well-known electrician, of Paris, has lately designed a series of ornaments for ladies' wear, which consist of glass, coloured and cut to imitate rubies, diamonds, &c., fitted in an envelope, surrounding a small incandescent lamp of low resistance. The light shines through the pieces of glass only, and gives them all the appearance of the stone they are intended to imitate. The lamp is fed from a small battery, which is carried about the person. It is composed of three pairs of zinc-carbon plates (two carbons to each zinc), or a larger number according to the current required. These plates dip in a saturated solution of bichromate of potash, which is contained by an ebonite cell with three compartments. The plates are fitted into a cover, which is kept securely down on the top of the cell by two bands of india rubber passed round the whole. Finally the battery is encased in two sheets of gutta percha, so as to entirely prevent any leakage. A miniature switch is carried in the pocket or elsewhere within reach, to which the battery and lamp wires are connected. The pressure of a finger on the arm of this switch makes or breaks communication with the lamp. The battery weighs (with six plates) 300 grammes, and will work about 30 minutes with a two to three-volt lamp. A larger battery to work a four or eight-volt lamp weighs 800 grammes.

Electric Lighting for Glasgow.—A public meeting of the warehousemen, merchants, and tenants whose premises are situated in the central section of the city of Glasgow was held in the Religious Institution Rooms, Buchanan-street, on Tuesday afternoon, Professor Simpson in the chair. Mr. Charles T. Grant said that the meeting had been called for the purpose of devising the best means of supplying electric light to the district. They had had in their offices between seven and eight thousand people, and every one was ready to take the electric light into his premises. The matter seemed to be that there should be formed a supply association for the purpose of lighting the district with electric light, by means of a central station. He and Mr. Turnbull, the engineer, had to some extent gone over the accounts with a view to ascertaining what it would cost to erect a central station. They calculated that a capital of £25,000 or thereabouts would be sufficient, and would be capable of giving 10,000 lamps. He found that in the central district of the city, from North-street to Glassford-street, gas last year cost £44,945 3s. If they were charging one penny per night for the electric light in the central district they would expend about £9,500, and the income would be about £15,258, which was a very creditable margin. A motion that a company should be formed for the purpose of supplying the city with electric light was afterwards adopted by the meeting.

Underground Wires in New York.—While in nowise opposed to electric light and telegraph wires *per se*, on the contrary very much in favour of their extension, we are nevertheless rejoiced to see any agitation pointing toward the removal from our city streets of the present unsightly and dangerous system. In the case now on trial in this city of the residents of Twenty-fifth-street *v.* the Brush Company, some valuable testimony has been brought out relating to the annoyance and positive danger to the ignorant or unwary from the close proximity of electric light wires to the homes of the complainants. Any one curious as to the number of wires for different purposes now enveloping in their meshes the business portion of New York has only to ascend to the top of the Mills' Building or any other elevated structure and see for himself; the only subject for wonderment is, where do they all go to? The existence of these wires when a fire occurs is already recognised as a potent source of danger to life and to property. The fireman finds them interfering with his endeavours to rescue the one and protect or save the other; and he is himself liable to be tripped up by wires running over the roofs, or to receive a perhaps fatal shock from a severed light wire. Insurance rates are increased, and the wires generally have developed into a first-class nuisance. Wires are added almost daily to the existing net, and these wires must be cared for by an army of *employés*; they are subject to all manner of danger to their efficiency; every fire destroys a number of them; each storm of snow or sleet causes extensive repairs; any evil-disposed person can tamper with them, to the annoyance or positive injury of the company's clientage. All this would be avoided in a properly constructed and well-managed conduit system.—*Engineering News*, of New York.

Too Vague.—The prospectus has been issued of "The Simplex Electric Light and Plant Company (Limited)." According to this document, it appears that the "company is formed for the purpose of purchasing certain letters patent for electric lighting on the arc and incandescent systems. These patents will give the company the sole right to make and supply simplex arc, and incandescent lamps throughout the United Kingdom." Further on we are told "the company will have power to grant concessions," &c. Again we read, "the Simplex arc lamp is distinguished from all existing arc lamps by extreme simplicity, low cost of manufacture, economy of working, and steadiness of light. It has been examined by Professor Sylvanus Thompson, and his report is in the highest degree favourable. The Simplex incandescent lamp possesses special advantages," &c., &c., &c., "the working of the lamp has been eminently successful, and the scientific tests it has undergone are conclusive as to its value." It is to be remarked that neither the numbers nor dates of the patents are given for either lamp, and that the name of the patentee is also withheld, though the lamps are endowed with a taking name. Then, again, Professor Thompson is said to have reported highly of the arc lamp, and the tests of the incandescent lamp are said to be "conclusive as to its value," but neither the report nor the tests are made public. The price to be paid for the arc lamp by the company is stated to be £3,000 in cash, £1,000 in six months, and an allotment of 600 fully paid shares; and for the incandescent lamp £3,000 in cash, £3,000 in six months, and an allotment of 600 fully paid shares. The granting of concessions is, in our opinion, and, to use a popular expression, played out. The case of the Brush companies would prove it, if nothing else did. Altogether, we think the above prospectus far too vague and unsatisfactory.

Electric Lighting for Dublin.—At a meeting of the Dublin Town Council held last week, the question of electric lighting came up for discussion, on the motion of Mr. McEvoy, who proposed that the Lighting Committee be instructed to take all necessary legal proceedings to restrain the Alliance Gas Company from erecting wires over the streets for the purpose of supplying electric light. In the discussion which followed the motion was opposed, on the ground that the

Digitized by Google

subject of overhead wires must soon come before Parliament' and that consequently it would not be advisable for the council to interfere with the Gas Company. The resolution, therefore, was not adopted. Meantime the Gas Company is at perfect liberty to erect as many wires as it pleases, and to deal in electric lighting as extensively as circumstances may require. We find it difficult to comprehend how the Dublin Gas Company finds itself in the enviable position of being able to supply the electric light without parliamentary or municipal authority of any kind. We have been under the impression that the Act of last year was passed with the specific object of bringing the business of electric lighting under proper control; and here we find a company engaged in the enterprise without even obtaining the formal permission of the local authority. The 14th section of the Electric Light Act, 1882, clearly points out that undertakers of electric light shall not be authorised to place any electric line above ground without the express consent of the local authority; and it further provides that the local authority may require the undertakers to forthwith remove any electric line placed by them contrary to the provisions of this section. In view of this legislation we fail to see how it is that the Dublin Corporation should be so neglectful of its privileges in not insisting that its authority should be respected, and in seeing that the provisions of an important Act of Parliament are complied with in its district.

The Sunda Straits Disaster.—An officer on board the United States man-of-war "Enterprise" makes an interesting report from Batavia on the great earthquake in the Straits of Sunda. In one part he says:—"About a week after we reached the Straits of Sunda we had a phenomenal sunset, awful in its grandeur, that terrified nearly all on board. Just before sundown the heavens became quite dark and then suddenly changed to a dark green. After the sun had sunk behind the horizon it became light again and the green tint gradually died away, the colour of the sky after a short while regaining its normal condition. On that very day and hour those terrible eruptions took place on the Island of Krakatoa, 700 miles away from us. Three days after this atmospheric phenomenon we noticed that the water was covered with a floating scum, which upon examination proved to consist of scoriæ and pumice." He adds the following graphic description:—"I have just seen the captain of an English ship that was near the island when the wrath of the storm and the earthquake fell upon it. He told me that the barometer just before any disturbance was noticeable began to fluctuate rapidly, dropping from 31 to 26 like a flash. He said that the atmospheric disturbances that soon followed, combined with the commotion of the waves, presented a picture that only hell as dreamed of by Milton could have equalled. Balls of fire crossed and recrossed the heavens and burst in mid-air, falling into the sea in innumerable fragments, accompanied by loud hissings. Heavy masses of clouds black as night rushed together from different points of the compass, and whirling around and around, seemed to be struggling for the mastery. Towering waves seemed to come from every point of the compass, and rushed together with terrific roars. Lightning leaped from the waves and was lost in the heavens. The wind, which was blowing cold, suddenly changed to a blast of heated air almost unbearable. The air was charged with electricity, and every man who took the wheel was instantly paralysed for the time being. Scoriæ began to fall as thick as snow. After his ship passed out of the storm the captain said that the scoriæ on the decks and rigging was so thick that it took fifty coolies three days to sweep it into the sea. The 'Juniata' has just returned from the scene and reports everything quiet now, with no indications of such another visitation being imminent."

Inventions and Inventors.—The beginning of inventions is very remote. The first idea, born within some unknown brain, passes thence into others, and at last comes forth complete, after a parturition, it may be, of centuries. One starts the idea, another develops it, and so on progressively, until at last it is elaborated and worked out in practice; but the first not less than the last is entitled to his share in the merit of the invention, were it only possible to measure and apportion it duly. Sometimes a great original mind strikes upon some new vein of hidden power, and gives a powerful impulse to the inventive faculties of man which lasts through generations. More frequently, however, inventions are not entirely new, but modifications of contrivances previously known, though to a few, and not yet brought into practical use. Glancing back over the history of mechanism, we occasionally see an invention seemingly full born, when suddenly it drops out of sight, and we hear no more of it for centuries. It is then taken up *de novo* by some inventor, stimulated by the needs of his time, and falling again upon the track, he recovers the old foot marks, follows them up, and completes the work. There is also such a thing as inventions being born before their time, the advanced mind of one generation projecting that which cannot be executed for the want of the requisite means; but in due process of time, when mechanism has got abreast of the original idea, it is at length carried out, and thus it is modern inventors are enabled to effect many objects which their predecessors had tried in vain to accomplish. As Louis Napoleon has said, "Inventions born before their time must remain useless until the level of common intellects rises to comprehend them." For this reason, misfortune is often the lot of the inventor before his time, though glory and profit may belong to his successors. Hence the gift of inventing not unfrequently involves a yoke of sorrow. Many of the greatest inventors have lived neglected; and died unrequited, before their merits could be recognised and estimated. Even if they succeed, they raise up hosts of enemies in the persons whose methods they propose to supersede. Envy, malice, and detraction meet them in all their forms; they are assailed by combinations of rich and unscrupulous persons to wrest from them the profits of their ingenuity; and last, and worst of all, the successful inventor often finds his claims to originality decried, and himself branded as a copyist and a pirate.—*Scientific American.*

Blasting by Means of Electricity.—In a contribution to the *Colliery Guardian*, entitled "Continental Colliery Notes," Mr. G. G. André remarks with reference to the blasting operations in the Arlberg tunnel:—"A notable feature of the Arlberg boring has been the firing of the blasts by means of the electric current. Though this method of firing cannot be claimed by the Arlberg blasters to be a novelty, they have been the first to apply it on a large scale in Europe; and the degrees of success they have achieved under unfavourable conditions is convincing proof that system is capable of giving satisfactory results. The unfavourable conditions to which I allude are those which relate to the generation of the electric current. For this purpose the old frictional machine has been used, with the inevitable result of occasional failures, and a constant inability to fire a large number of shots simultaneously. I cannot help thinking that in this matter the Arlberg engineers have shown a a want of shrewdness and appreciative ability, all the more striking as the means they were in need of not only lay

Digitized by Google

visible about them, but were thrust upon their notice by other considerations. The cause of the non-success or the partial success of all attempts hitherto made to employ the electric current for the simultaneous ignition of numerous shots in the ordinary circumstance of mining lies wholly in the feebleness of the current employed. The machines in use will fire, with a fair degree of certainty, from three to five shots at a time. But nearly all the advantages of the system are lost if the whole number of shots in the heading cannot be fired at once, and this, with the means in use, has been found to be impossible. Hence the system, introduced years ago, has made but little headway, especially in this country. Let me relate my own experience, obtained at no little cost of money and time, to prove that the cause of failure lies in the insufficient quantity of the current generated by these machines. I obtained a machine capable of igniting a few fuses. With three in series I succeeded in exploding all of them sixty-three times out of one hundred; in the other thirty-seven experiments only two were fired. Taking now from the same lot of fuses, and using the same instrument, I exploded 5,000 single shots without a misfire. This was sufficient to convince me that all that was needed to bring down the entire heading at once with almost absolute certainty was a powerful electric generator. Now the numerous advantages and great economy of the electric incandescent light in tunnelling point it out for adoption in every important undertaking. A driving so lighted is provided with the means of firing the blasts in any required numbers, for the current has only to be shunted for a moment from the lamps into the fuses to ensure their ignition. I have dwelt upon this question because I regard it as destined shortly to assume great importance. That the electric light will soon make its way into all mining workings hardly admits of a doubt; and the electrical ignition of the blasts would seem to follow as a matter of course. The greatly increased effects of the simultaneous ignition of all the shots in the face of a heading or the bottom of a sinking, and the relative safety which this method of firing gives, are advantages of no mean importance, and the prominence given to the system in the driving of the Arlberg tunnel cannot fail to attract the attention of all concerned in similar undertakings."

Provisional Orders.—There is a marked falling of in the number of applications for provisional orders this year as compared with last, the cause, or rather causes, of which it is not hard to discover. Beginning with electric lighting we find that the Bury St. Edmunds Corporation request power to produce, supply, and store electricity as defined by the Electric Lighting Act. The area to be lighted at first is "Cornhill, including the town hall, butter market, meat market, provision market, and corn hall, Abbeygate-street, Brentgovel-street, from St. Andrew's-street to Well-street," but the corporation particularly specify that they do not wish to confine themselves to this area.—The Telegraph Construction and Maintenance Company and the West London Electric Lighting Company will apply for an order transferring or vesting in them the rights or powers granted to the Edison Company in respect of the parishes of St. James's, Westminster, and St. Martin's-in-the-Fields, by the St. James's and St. Martin's Electric Lighting Order, 1883, and the Electric Lighting Order Confirmation (No. 5) Act, 1883, respectively.—The St. Helens (Lancs.) Corporation require an order permitting them to supply electricity for "public and private purposes," as defined by the above-mentioned Act, as also do the Bootle-cum-Linacre Corporation.—The West Middlesex Electric Lighting Company wish to supply electricity within the area of the Fulham District Board of Works, and "the streets and roads along which it is proposed to place electric lines are the streets and roads within such area, and more particularly Hammersmith-road, King-street East and West, Broadway, Bridge-road, Walham Green, Fulham Old Town, Goldhawk-road, Shepherd's Bush Green, Brook Green-road, Fulham-road, North End-road, New King's-road, The Grove, and the streets and roads in the Cedars Estate."—The Westminster District Electric Lighting Company want to supply electricity within the district of the Westminster Board of Works, and have given notice that they will apply for a provisional order to enable them to do so. They "more particularly" wish to supply electricity within the following area, viz.:—"Vauxhall Bridge, Vauxhall Bridge-road, Francis-street, Grosvenor-road (east of Vauxhall Bridge-road), Lambeth Bridge, Horseferry-road, Strutton Ground, Victoria-street, Tothill-street, Broadway, Queen Anne's-gate, Birdcage-walk, The Mall, Great George-street, The Sanctuary, Bridge-street, Westminster Bridge, St. Margaret-street, Old Palace-yard, Parliament-street, Downing-street, Whitehall, Whitehall-place, Great Scotland-yard, Knightsbridge, Kensington Gore, Rutland Gate, Prince's Gate, Exhibition-road, Prince's-gardens, and Montpelier-square." And here ends the record of applications for provisional orders, so far as electric lighting is concerned, with the exception of the Edison-Swan application, which we noticed at page 46 of our issue for the 24th ult. There also will be found a brief notice of the provisional orders applied for by the United Telephone Company, the India Rubber, Gutta Percha, and Telegraph Works Company, and the Mid-London and London Central Electric Railways. It remains to notice a few miscellaneous items in the applications for other provisional orders. To begin with, the Dewsbury (Yorks) Corporation will ask for powers "to prohibit the fixing, placing, or attaching of any wire, tube, or other apparatus for telegraphic, telephonic, or electrical purposes over any street, road, or public thoroughfare, except with the consent of the corporation, and on such terms and conditions as they shall deem expedient to prevent obstruction, danger, or annoyance to the traffic, or to passengers therein, and to empower the corporation to inspect any such tube, wire, or apparatus (whether existing or future), and the supports and attachments thereof, and to order the repair, alteration, renewal, or removal thereof respectively, and in default thereof to enable the corporation to execute the requisite works themselves at the cost of the owner or hirer thereof, and to exercise all such powers of entry on premises as may be necessary for the purposes aforesaid, and to relieve the corporation from all liability by reason of any failure of, or accident from, any such wire, tube, apparatus, or works."—In their application for power to construct tramways, the Blackpool Corporation want to reserve "the exclusive right of using on any of the tramways, carriages drawn or propelled by animal, steam, gas, or compressed air, electricity, or other power."—Finally, the Croydon Corporation will ask Parliament to authorise them "to provide and maintain for their establishments or offices telegraphic or telephonic communication between any parts of the borough, and for such purposes to incorporate, extend, or apply all or some of the provisions of 'The Telegraph Act, 1863,' or any other Act or Acts amending the same." Also to empower them "to prohibit or regulate by license or otherwise the placing or maintaining of wires, conductors, cables, tubes, or other projections, works, or things, above, along, across, or beneath streets or other public places within the borough."

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 55.)

**Polarisation of Electrodes.**—In consequence of the alteration both of the chemical composition of the surface of the anode and of that of the cathode, and also of that of the layer of liquid in contact with each of the electrodes by electrolytic action, the electric state of each of these surfaces is continually liable to change; or, in other words, the surfaces become polarised. And as the substances set free at the anode are usually electro-negative, and those at the cathode are usually electro-positive, the electric states produced by polarisation are opposite in kind to the original ones, and tend to produce an electric current in an opposite direction to the previous one, and therefore weaken that current. According to M'Gregor (*Nature*, July 19, 1883, p. 283), the degree of polarisation of electrodes is independent of their degree of difference of potential. By passing an undivided current by means of four similar platinum sheet electrodes through two cells containing equal sections but unequal lengths of dilute sulphuric acid (the current being therefore of equal density in each and the electrodes of the two vessels of unequal potential), he found that the variation by lapse of time of the electromotive forces of the two cells after cessation of the polarising current was similar.

**Unequal Electric Action at Electrodes.**—By the electrolysis of a metallic electrolyte by means of vertical corrodible electrodes, the liquid around the anode usually becomes more saturated with metallic salt, and being heavier descends, whilst that around the cathode becomes deprived of metal, acquires less specific gravity, ascends, and spreads itself over the surface. In consequence of these variations in specific gravity of the upper and lower parts of the electrolyte, the direction of the current in it is gradually affected. At first, whilst the liquid is uniform in density and composition throughout, the whole of the current is perfectly horizontal in direction, and equal amounts of it pass through equal sections of the liquid; but, if the current is sufficiently strong, after a while it passes unequally, and the bulk of it travels in an oblique direction from the upper part of the anode to the lower part of the cathode. In consequence of this, the greatest amount of electrolytic effect is at those parts of the electrodes, and thus in some cases the upper part of the anode is rapidly corroded, whilst the lower part of the cathode receives a rapid deposit. If, however, the current is very feeble, the liquid is kept uniform in composition by means of diffusion as fast as it is rendered non-homogeneous by electrolysis; if also the liquid is very viscous and diffusion difficult, these phenomena are more slowly produced. These changes in composition of the upper and lower parts of the liquid also give rise to local currents, which leave the upper part of each electrode and re-enter at its lower portion, and produce the usual electrolytic effects. With the electrodes horizontal, and the cathode below the anode, the above inequalities of electrolytic action do not occur.

In some cases, apparently in consequence of a very thin layer of corrosive liquid collecting upon the surface of the electrolyte by long-continued rapid electrolysis, the anode is gradually cut off at that level and falls to the bottom; in other cases, partly in consequence of evaporation, of oxidation of moist metallic surfaces by the air, and of capillary action, the cathode is corroded in numerous short vertical grooves at the surface line of the liquid, and a narrow line of metallic deposit gradually forms above the surface of the liquid, and follows the outline of the narrow film of liquid which has risen by capillary action. A probably correct explanation of the formation of this deposit is that the capillary film of liquid becomes much less corrosive and more saturated with the metal by chemical action than the bulk of the liquid beneath. The piece of metal is therefore in contact with two liquids of different chemical composition, and a voltaic element is thereby formed, and generates a current, the positive electricity of which proceeds from the portion of surface of metal which is in the upper and nearest part of the bulk of the solution into that solution, thence to the capillary film, and into the narrow surface of metal in immediate contact with it, and thus corrodes the metal just below the surface of the liquid, and deposits the metal in the capillary film. This phenomenon is seen in alkaline liquids as well as in acid ones; for instance, with silver in a solution of potassic cyanide.

The corrosive effect attending this capillary action differs somewhat with different metals and liquids. With metallic tin, in particular, in dilute hydrochloric acid, in some experiments of mine, grooves about ·5mm. deep were corroded in its surface and extended in a vertical direction to a distance of nearly 7mm. above the level of the liquid. The grooves were crooked, and had branches like those of a tree, and those upon the cathode were longer and deeper than those on a similar sheet of metal in a separate portion of the same liquid not under electrolysis.

**Dependence of Electrolysis upon Liquid Diffusion.**—This is a branch of the subject which has hitherto been but little examined, and much remains to be discovered in it. Many of the phenomena of electrolysis are, no doubt, essentially related to the power of liquid diffusion. An extremely viscous liquid admits of but slow electrolysis. Long has discovered (*Phil. Mag.*, 1880, Vol. IX., p. 425) that in almost every case the best conducting saline electrolytes are solutions of those salts which have the fastest rate of diffusion, and those are usually the salts which have the largest molecular volume, and which also absorb most heat in dissolving. He also arrives at the conclusion that "the rate of diffusion of a salt is proportional to the sum of the velocities with which its component atoms move during electrolysis."

**Electrolytic Diffusion of Liquids.**—I have experimentally investigated this converse part of the subject (*see Proceedings of Royal Society*, No. 203, 1880, p. 322, and No. 212, 1881, pp. 56—84), and have shown that an electric current will cause a liquid to diffuse, and I discovered that when such a current was passed up or down through the surfaces of mutual contact of certain aqueous solutions of different specific gravities lying upon each other in well-defined layers, the bounding surfaces of contact of the two liquids became indefinite where the current passed downwards from the lighter to the heavier solution, and became more sharply defined where it passed upwards from the heavier into the lighter one; and that on reversing the current several times in succession, after suitable intervals of time, these effects were reversed with each such change of direction; also, in various cases in which the contiguous boundary films of the two liquids had become mixed, and the line of separation indefinite, the liquids separated by the influence of the upward electric current, and the line of separation became as perfect as that between strata of oil and water lying upon each other. I also observed, 1st, the production of definite lines, not only where the current passed from the heavier into the lighter solution, but also (in certain cases) at the surface where it passed from the lighter to the heavier one. 2nd. The production in some cases of two or three separate lines at the former situation, and less frequently also at the latter one. And, 3rd, an apparent movement of the mass of the heavier solution, usually in the direction of the electric current, but in certain exceptional cases in the reverse direction. By further experiment (*see Proceedings of the Royal Society*, No. 217, 1881, p. 141) I ascertained that, 1st, in certain cases the upper and lighter liquid diffused downwards continuously through the meniscus, or surface of separation of the two liquids, during the passage of an upward electric current; and, 2nd, that during the continuance of the current either no manifest expansion of the upper liquid occurred, and that equal volumes of liquid diffused in two opposite directions through the meniscus, or that any expansion of the upper liquid was compensated by downward diffusion of an equal bulk of that liquid; or that the united volumes of metal deposited from the upper liquid, and of the acid element from which it had been separated by electrolysis, were greater than before such

Digitized by Google

separation, and that this was compensated by the volume of liquid diffused downwards through the meniscus. In these latter experiments the meniscus retained its position during the passage of the current, thereby proving that the actual bulk of the upper liquid remained the same whilst diffusion of a portion of that liquid took place downwards through the meniscus.

**Transport of Ions.**—Hittorf and G. Wiedemann found that usually the velocity of transport in electrolysis of anion and cation are different, and F. Kohlrausch discovered that in dilute solutions of salts, acids, and alkalies, every ion under the influence of currents of equal density moves with its own particular velocity, independently of others moving at the same time in the same or opposite direction. The order of velocity of cations, the first named being the fastest, was hydrogen, potassium, ammonium, silver, sodium, barium, copper, strontium, calcium, magnesium, zinc, lithium; and of anions was hydroxyl, iodine, bromine, cyanogen, chlorine, $NO_3$, $ClO_3$, and the halogen of acetic acid.

**Relations of Electrolysis to Heat.**—In consequence of chemical action and of the passage of an electric current from one substance to another, changes of temperature occur at each electrode, and at each junction of two different liquids. These changes are different in every different case, and have been but little investigated. With an anode of copper in an acidulated solution of its sulphate, heat is evolved by the oxidation of the metal; but with one of platinum in dilute sulphuric acid, heat is absorbed, and oxygen is reduced to the elementary state. At the cathode, in the former liquid, copper is liberated and heat absorbed; but with a platinum cathode in nitric acid, heat is set free by oxidation of the deposited hydrogen.

According to Favre (*Comptes Rendus*, Vol. LXXIII., pp. 1,036—1,085, 1,186—1,262), although in certain cases the metal dissolved at the anode is all reproduced at the cathode, heat is liberated which is not transmissible to the circuit. The oxides and salts of the alkali metals, when subjected to electrolysis, are decomposed, and give up their metal, which metal being *directly oxidised* at the expense of the water, sets free a quantity of heat which reinforces the voltaic energy of the battery. The secondary reactions which accompany electrolysis and produce heat not transmissible to the circuit, always tend to strengthen the energy of the battery whenever the current is weak and when the electrolysis offers great resistance. Such secondary reactions are, for example, produced by the hydrogen and the oxygen set free during electrolysis, the first being burned, the second oxidising any oxidable substance present. (*Journal of the Chemical Society*, 2nd series, Vol. X., pp. 110—113.)

In addition to changes of temperature produced by electrochemical and chemical actions in the electrolyte, heat is evolved by conduction-resistance in the mass of the liquid; and I have noticed that if two large masses of the same, or of two different electrolytes, are united by an open short glass tube of the shape of an hour glass, and of small diameter, by employing a sufficiently strong current the liquid in the narrow part of the connecting tube may be caused to boil. ("Influence of Voltaic Currents on Diffusion of Liquids," *Proceedings of the Royal Society*, 1881, No. 213, pp. 76—82).

Gladstone and Tribe have shown by experiment that if a strip of metal is immersed at its two ends in a salt of the same metal in a state of fusion, but of unequal temperature at the two parts where the metal dips into it, the hotter end of the metal dissolves, and the less heated part receives a metallic deposit. Copper in fused cupric chloride is an example (*Journal Chemical Society*, Vol. XL., 1881, p. 868.)

EASTERN TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of November amounted to £49,390, and to £54,098 in the corresponding period of 1882.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 34.)

In 1880 M. T. Carpentier brought to the notice of the Société des Anciens Elèves des Ecoles Nationales d'Arts et Métiers (*Bulletin* of the society, No. 186, p. 285) a brake which is founded upon the same principle as Imray's. Although coming long after Imray's, and from a mechanical point of view decidedly inferior to it in design, a short description of Carpentier's brake must here be given, because it appears to have been the basis upon which M. I. Raffard designed his very successful "dynamometrical balance," which was shown at the Paris Electrical Exhibition in 1881.

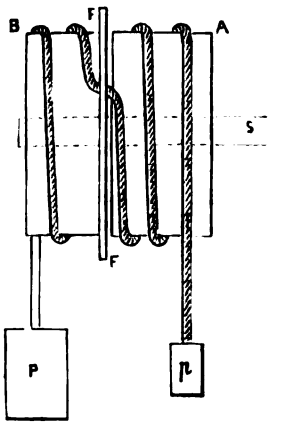

FIG. 5.—Carpentier's Brake.

The shaft *s*, Fig. 5, of the prime mover carries two pulleys, A and B, of which the former is keyed to it, whilst the latter is loose. Pulley B is provided with a flange, F F, to which is fastened the middle of a rope which is coiled to either side round the pulleys, as shown. If the brake is in equilibrium, B remains stationary, and A rotates with the shaft, at the same time slipping under the coils of the rope. The end of this rope is kept tight by a small weight, *p*. The direction

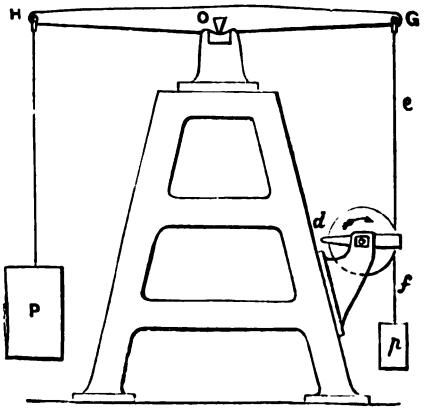

FIG. 6.—Reckenzaun's Brake.

of movement is such as would wind up the larger weight P if the coils on it would not slip. It will easily be seen that this brake is in stable equilibrium; for, imagine that by an accidental excess of friction on A the weight P were actually wound up, then the length of coils on B would increase by a certain amount, and that of the coils on A would at the same time be diminished by precisely the same amount. Hence the grip of A on its rope will also diminish, and that will go on so long until the rope again begins to slip, and equilibrium is re-established. The analogy of this apparatus with Imray's brake (Fig. 4) will be seen at a glance. The cast-iron segment of the latter is here replaced by the loose pulley B, and as regards the brake-pulley proper the only difference is that Carpentier employs several convolutions of rope, whilst in

Digitized by Google

Imray's brake the band embraces only part of the circumference. In the paper above quoted M. Carpentier says that his brake can only be used for small powers (say one, or at the most two, horse-power), but that it is so accurate that, enclosed in a calorimeter, it might be used for the determination or verification of the mechanical equivalent of heat. M. I. Raffard improved this brake, so that it could be used for measuring up to six horse-power (*see Bulletin*, No. 212, page 467), and Mr. A. Reckenzaun, of the Electrical Power Storage Company (Limited), has again introduced some

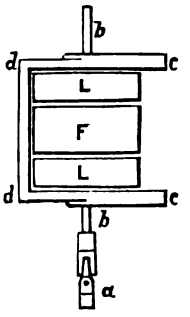

Fig. 7.—Reckenzaun's Brake.

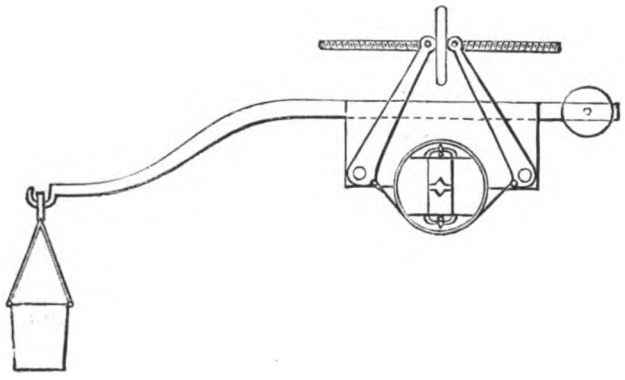

Fig. 8.—Prony Brake for Testing Motors.

improvements in the details, making it applicable for even larger powers. The author is indebted to Mr. Reckenzaun for the drawing of his brake, which is shown in Figs. 6 and 7.

The prime mover is connected to the brake by means of

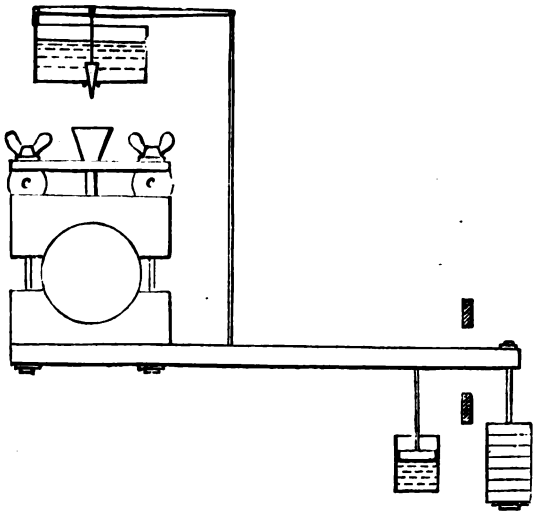

Fig. 9.—Raffard s Brake.

the universal coupling *a* (thus doing away with the necessity of having motor and brake shaft rigidly in line); *b b* are the bearings of brake shaft, to which is keyed the fast pulley F, whilst two other pulleys, L L, are loose on it. The weight *p* hangs on a band, *f*, which takes one half turn over the top of the fast pulley, and is fixed to crossbar *d d*; two other bands, *e*, fixed to the same crossbar, and taking each a half turn under the loose pulleys, are attached to the end of lever G H, and the pull in these bands is counterbalanced by a weight, P. To ensure great delicacy the lever rests upon a knife edge centre gudgeon O. The crossbar *d d* is counterbalanced by the extended arms *c c*, filled with lead. The three brake pulleys are placed inside a trough with removable hood, and during tests this trough is kept filled with soap water, partly to cool the brake, and partly to ensure that the co-efficient of friction may remain as constant as possible. For convenience of calculation the size of pulleys is so arranged that their circumference is one metre in the large brake (up to 10 h.-p.), and half a metre in the smaller brake (up to $2\frac{1}{2}$ h.-p.). If Q be the difference $P - p$ of weight in kilogrammes on both sides of the lever, and $n$ the number of revolutions per minute, then the work in kilogrammetres used up in the large brake per minute is

$$W = Q\,n,$$

and in the smaller brake

$$W = \frac{Q\,n}{2}.$$

To get horse-power divide W by 450.

The advantage of Raffard's brake is that it requires no tightening of screws nor care for lubrication as does the Prony, but simply the adding or taking away of weights until the lever is horizontal and the speed is as desired, thus requiring very little skill to handle it. Its disadvantage is that the prime mover must be placed at least approximately in line with the brake shaft, so that the motion transmitted by the universal couplings should be as uniform as possible, and also that on account of the small diameter of brake pulley the friction is not very constant, to say nothing of the inconvenience of splashing about of soap water.

For accurate tests a properly designed Prony brake of ample size is preferable. Fig. 8 shows the form used by Mr. Reckenzaun for the testing of electro-moters. The brake pulley is provided with a pair of jaws by means of which it can be clipped on to the spindle of any motor somewhat in the manner of a lathe chuck. A right and left handed screw with large handwheel is used to tighten both ends of the brake band simultaneously, thereby pressing the pulley against the top brake block, which is of hard wood. The lever is curved downwards and the weights are placed into a deep basket, by which means the equilibrium of the brake is made stable.

Several attempts have been made to automatically vary either the co-efficient of friction or the pressure between brake blocks and pulley. One of these designs by Raffard is shown in Fig. 9, where a somewhat elastic pressure on the pulley is obtained by interposing springy washers, *c c*, between the tightening nuts and the top brake block. The co-efficient of friction is varied automatically by varying the supply of soap water from a tank placed above the brake. An excess of friction will draw the lever up, thereby opening to a larger extent a valve in the bottom of the tank, thus admitting more lubricant, which, by reducing the friction, checks the rise of the lever. Another method, also due to Raffard, for automatically varying the friction is by the employment of a third wrought-iron brake block, which is the pole of an electro-magnet, the pulley being its armature. The electro-magnet is excited by a current traversing a variable liquid resistance. If the lever sinks the resistance decreases the current, and the attractive power of the electro-magnet increases and puts more and more friction on the third brake block, until this excess is sufficient to re-establish equilibrium. It should be mentioned that the two main brake blocks are set as near as possible to the right pressure, so that the magnetic brake has only to make up for small variations.

## CORRESPONDENCE.

### PRIMARY BATTERIES FOR ELECTRIC LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: An article in your issue of to-day on "Primary Batteries for Electric Lighting" leads me to think that the enclosed copy of a report on my battery may be of interest. It was made by a professional tester, formerly in the General Post Office, for one of the large electric light and power companies, and he had my battery for a fortnight under his entire control. I take the liberty of enclosing it for your perusal, but not for publication.

You will observe that he gives as the average consumption of zinc three-quarters of a pound per horse-power per hour, and, using cast spelter, the price of this is under twopence per pound.

The small consumption seems to prove that part of the current is obtained from the inter-action of the liquid electrolytes. His results are corroborated by very numerous similar tests made by myself.

I venture to point out to you that a substitution of these figures for those in your article would modify your equation thus: $\frac{1{\cdot}5 \times 5}{200} = 0{\cdot}0375$d per hour per 5-candle lamp, or 0·15d per hour per lamp of 20 candle-power, and only 2d. per hour for the electrical unit of 1,000 volt-amperes, for which Messrs. Gülcher and Edison are to charge in the City respectively 8½d. and 9d.

Moreover, in my battery the zinc is recovered in augmented volume, and as a *solid* at the bottom of the cells in the form of oxychloride of zinc, a valuable product because forming the principal ingredient of a new insulating material resembling india rubber.

My batteries have been seen and examined by numerous visitors, and I should be very happy to place a few cells at your disposal for testing purposes if ever you should deem them worth examination.—Yours, &c.,

O. C. D. Ross, M. Inst. C. E.

15, Relf-road, S.E., Dec. 1, 1883.

---

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your impression of the 1st inst. you refer, though indirectly, to a system of lighting by primary batteries, in which the cost is brought as low as 0·125 of a penny for each 5-candle lamp. You proceed to estimate the minimum cost of the light at 0·15d. per hour even when disregarding the cost of the electrolyte. As there is but one system which has been "talked of by your daily contemporaries" in the way you describe, and as your remarks are not calculated to leave a favourable impression on the minds of your readers, I may, perhaps, say a word or two in defence. You appear to have overlooked an important condition, an essential one in the economy of this battery, viz., *that the residual products, by reason of their commercial value, are marketable.* You will readily acquiesce in the proposition that the sale of the *residues* being stopped, the price of illumination by means of gas would be enormously increased. Why, then, draw the line at gas retorts? Why not extend the same principle to a primary battery? Of course every electrician knows that with zinc alone the cheap generation of electricity is hopeless, but it is also a fact that when the circumstances of a case are represented in their entirety one has a better opportunity of judging the merits thereof.—Yours, &c.,

A. HAMILTON-CHURCH.

Uxbridge, Dec. 3, 1883. Mem. Soc. Int. des Elec.

---

### DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am quite aware "that if a piece of iron be placed across the poles of a magnet there will be very little external field." Knowing this, my dynamo is designed to avoid the error. I fancy from "A. B.'s" letter that he must have made some such mistake himself at one time. I have ascertained that Mr. Oldham's machine is similar to mine, therefore what I wrote I think will hold good.

Mr. Hitchcock is, of course, quite right in what he says concerning the Edison, &c., dynamos. Mr. Oldham's is this type inverted as regards the field magnets, the bed plate forming the junction between the legs of the field magnets, the armature revolving in gun-metal bearings between the poles, so that there is no iron whatsoever "placed across the poles." Thus the bed plate forms a connection "between parts of field magnets at the same magnetic potential."

This being the case, no one has yet solved Mr. Oldham's difficulty, and in the meantime my partly completed machine is also at a standstill.—Yours, &c., W. T. FARQUHAR.

Forfar, N.B., Dec. 3, 1883.

---

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am afraid the description of my defective dynamo has given rise to some misunderstanding among your correspondents, causing me to be credited with the undreamt-of folly of (magnetically) connecting the poles of my field magnet, which, of course, is not the case.

The machine is of the horseshoe type; but the horseshoe takes the form of three sides of a square. *The middle side is the sole, or bed plate,* and is bolted to a wooden base. The two other sides are the cores wound with wire, and surmounted by pole pieces. Between these the H armature revolves, forming, as it were, the fourth side of the square.

The fault, I think, is somewhere in the proportions of wire and iron in the A and F M, which I gave fully in my first letter. But where?

I find I miscalculated the number of revolutions. I should have said at least 1,000 per minute.—Yours, &c.,

Dec. 1, 1883. R. W. OLDHAM.

---

### SECONDARY GENERATORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your correspondent "Enquirer," whose letter you publish in your issue of the 1st inst., says he is puzzled, firstly, as to why these apparatus are called secondary generators; and, secondly, as to their efficiency. I will try and help him out of his difficulty.

To begin with, what is "induction"?

Is not what we call "induction" the peculiar phenomenon manifested by electricity when two bodies are in proximity, one charged either statically or dynamically, and the other uncharged? Does not the uncharged body become charged by the influence of the one which is charged? Certainly it does, but so long as we speak of this effect of *current* upon *wire* we call it "induction;" whilst when we come to speak of this same effect produced by the action of *magnets* upon *wire* we call it "generation," as if there was any difference. Is this reasonable? A dynamo machine is as much an "induction" machine as is any secondary generator; both generate current by induction, only the one does it *indirectly*, whilst the other does it *directly*.

Let "Enquirer" think for a moment. What produces the current in an ordinary dynamo? Is it not the movement of the coils of wire cutting the magnetic field? Here the coils move through a stationary magnetic field, whilst in the secondary generator the magnetic field moves through the stationary coils, the moving magnetic field being in this case the alternating current. In the first instance the movement is produced by rough mechanical power, in the second by the delicate alternations of the primary current. The difference in the effect is very perceptible. The rough mechanical power when applied direct produces unsteadiness in the lights, whereas when applied through the medium of the delicate alternating current absolute steadiness is secured by reason of the great difference in the ratio between the irregularities of the steam engine and the enormous number of the alternations per minute of the primary current. Let "Enquirer" call the apparatus "induction coils" if he prefers, but it will not alter the fact of their being *generators* after all.

As to the efficiency of the secondary generators, it is as

Digitized by Google

well, of course, that "Enquirer" should wait "patiently," if he has to wait at all. To wait impatiently would not be pleasant for him or his friends; but I see no reason why there should be any waiting.

Let him pay a visit to our engine room at the Edgware-road Station, and judge for himself from what is being actually done. This will prove to him whether the loss is great or not; but I would here remark that did the secondary generator but give back only 25 per cent., the other advantages secured would alone give it a position of pre-eminence among systems for distribution. However, instead of only 25 per cent., the return is more like 90 per cent., as I can show him should he care to pay a visit.

Your correspondent "Brevity" is right as to the dreadful length of most electrical companies' titles, but what is one to do? If you have to describe a thing, it cannot, unfortunately, be done always in one word. However perfect the English language may be, it has not yet reached that perfection.

There are many interesting technical points in connection with the secondary generator which I should like to bring before your notice when convenient to you.—Yours, &c.,

J. KENNETH D. MACKENZIE.

18, Warwick-street, Regent-street, W.
Dec. 3rd, 1883.

## A NEW ENERGY METER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following is a short account of a recent invention which I have made and put into practical operation in the Physical Laboratory of the College of New Jersey:—

The invention relates to the measurement of the energy expended on a dynamo or a magneto-machine when used as a generator, or rendered when such machine is used as a motor.

The machine is so constructed that the field-magnet system can freely turn through a small arc of a circle whose centre lies in the geometrical axis of the armature. In order to do this two extra uprights are secured to the base (of zinc or other non-magnetic material) on which the whole machine is built. These uprights have a height and position such that the bottom of a groove in the top of the one and the bottom of a conical cavity in the top of the other lie in the prolongation of the geometrical axis of the armature. To the top of the field magnet system is attached a girder, furnished at either end with steel rods, projecting downwards, and ending, the one in a knife edge, and the other in a conical point. These rods are adjusted so that when the knife edge rests in the groove and the point in the conical cavity, the armature is in its proper relation to the field magnets—that is, it is centrally placed in the magnetic field.

Now, when the machine is in operation the mechanical couple set up by the action of the armature on the field magnets tends to make the system revolve in the same direction with it.

It is this couple whose value we desire to know. It is determined if we know the value of the couple, opposite in direction, required to hold the field magnets fixed. A lever arm is attached to the field magnets, in a horizontal direction, and on this moves a sliding weight of known value, which can be so adjusted as to hold the magnet system in equilibrium. Knowing now the length of the lever arm, and the value of the weight, we have only to ascertain the number of revolutions in a unit of time, and we have all the data required for computing the energy expended or given out according as the machine is used as a generator or as a motor.

The formula is $2\omega L W n$, where $\omega$ has its usual signification (3·141592). L is the length of the lever arm, determined by the position of the sliding weight, W is the value of the weight, and $n$ is the number of revolutions in a minute.

It is to be noted that the result is quite free from all uncertainty arising from friction at bearings, brushes, &c., since these do not come into the account at all. It is clear, therefore, that a machine constructed as described above possesses advantages for experimental inquiry which can hardly be secured in any other way.

Several machines, which have variable members, and which are mounted in accordance with the plan set forth, have been installed in the physical laboratory of this institution, and have proved in every way satisfactory.—Yours, &c.,

C. F. BRACKETT, Professor of Physics.

Physical Laboratory, College of New Jersey,
November 23, 1883.

## MR. HERRING AND THE POST OFFICE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The death of Sir William Siemens makes an important gap in my telegraphic acquaintance. It is interesting to recall the changes I have experienced since as an outsider I took pleasure in following and striving to advance the essentials of the science.

Poor Culley, the first engineer-in-chief of the Telegraph Department, who said my system would not produce readable signs, and after it had been proved to print 1,600 in a minute accurately, said there was nothing new in it, he, too, has gone. Poor Scudamore, with his bland politeness and silvery voice, who proposed to refer my invention to arbitrators, and persuaded me to provide both transmitting and receiving instruments for the use of these arbitrators, who induced me to name, and to pay, two eminent scientific men to meet two arbitrators nominated by the Post Office, who obtained possession of the instruments years ago, and yet never to the present hour brought the arbitrators together, he, also, has gone. Henry Shephard Law, the solicitor to the Commissioners in Lunacy, who was employed by me to arrange the terms of arbitration with Mr. Scudamore, is dead. John Marshall Hayman, who wrote a masterly "counsel's opinion" upon the matter, is also dead. Wheatstone, who invited me to Park-crescent to discuss the invention, and expressed his approval of it, is dead. Becker, foreman to Elliott Brothers, who did likewise, but said he dared not make the instrument, as his firm supplied the Post Office, but gave me the name of Theiler. He, too, is dead. Theiler, recommended by Becker in writing to make an instrument to my order, and who made it, is dead. Isherwood, the Post Office surveyor of private wires, who expressed his opinion in favour of my system, was shortly afterwards dismissed. Valentine, the fastest bell clerk in the Post Office service, who was selected by the department to work my instruments and found them efficient, is also dead. I have his memorandum stating that 40 words a minute can be easily printed by my instrument, and that a message of 75 words only occupied 62in. on the paper slip. Now I have to add the name of Sir William Siemens to the long list of my lost telegraphic acquaintance. The nature of my association with him will be best told by the correspondence I have had with his firm, which I send, and which many of your readers might read with interest and advantage.—Yours, &c.,

RICHARD HERRING.

27, St. Mary's-road, Canonbury,
Dec. 3, 1883.

[The correspondence here referred to is so lengthy that we are quite unable to publish it in full.—ED. *E.*]

## UTILISATION OF NATURAL FORCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A discrepancy in the paper headed "Utilisation of Natural Forces," issue November 10, has not apparently been noticed. Mentioning Mr. Volk's proposal to obtain large quantities of hydrogen and oxygen by electrolysis, it is stated that 131,000 ampere-seconds will be required to give 1lb. of both gases. So far from this being the case, it takes 4,798,800 ampere-seconds, or 1,333 ampere-hours, to evolve that weight. This is clear from the datum given, viz., that a current of one ampere will decompose 0·0000945 gramme of water per

Digitized by Google

second. We have, therefore, 0·342 gramme per hour by the same current, and if we take 1,000 amperes we have 340·2 grammes decomposed per hour. Therefore it will take $\frac{453·6}{340·2} \times 1{,}000 = 1{,}333$ ampere hours to liberate 11b. of mixed gas.—Yours, &c.,

H. D. WILKINSON.

## HUNNINGS' TRANSMITTER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you please inform me in your next issue whether the Hunnings transmitter is (after the late trials) open to be used by the public.—Yours, &c.,

A SUBSCRIBER.

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 59).

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

### HISTORY IN RELATION TO TELEGRAPHY.

Around the magnet, Faraday
Is sure that Volta's lightnings play,
But how to draw them from the wire?
He took a lesson from the heart—
'Tis when we meet—'tis when we part
Breaks forth the electric fire.

*Impromptu*, by Herbert Mayo, in *Blackwood's Magazine*.

From an early period in the history of electricity philosophers began to point out strong resemblances between the phenomena which it exhibits and those of magnetism. In both sciences there existed two forces of opposite kind, capable, when separate, of acting with great energy, and being, when combined, perfectly neutralised and exhibiting no signs of activity; there was the same attraction and repulsion between the two magnetisms as between the two electricities, and according to the same law of inverse squares; the action of free electricity on a neighbouring body was not unlike that which a magnet exercises upon iron; and, lastly, the distribution of the two forces in the one seemed to differ little from that of the two forces in the other.

These analogies were powerfully supported by several facts. Thus, as early as 1630 Gassendi observed that magnetism was communicated to ferruginous bodies by lightning; the compass needles of ships were known to have their poles weakened, and even reversed, by a similar cause—a fact first recorded by English navigators in 1675; and, in 1750, Professor Wargentin remarked that delicately-suspended magnets were affected by the Aurora Borealis.†

With such analogies, and supported by such remarkable facts as these, the suspicion was but natural that the two sciences were allied in some close and intimate way, and accordingly we find that, about the middle of the last century, the discovery of this relation became a favourite pursuit.

Swedenborg was the first to boldly express his views on this subject in his "Principia Rerum Naturalium" (Dresden, 1734), in which he argued a close relationship between electricity and magnetism on the ground of their both being polar forces.

In 1748, Beraut, professor of mathematics in the College of Lyons, published at Bordeaux a thin volume of 38 pages,‡ which is probably the first distinct treatise on its subject, and which also goes to show that a true connection exists; that, in fact, it is the same force only differently disposed, which produces both electric and magnetic phenomena.

In studying the points of analogy between lightning and electricity, the great Franklin remarked that the latter, like the former, had the power not merely of destroying the magnetism of a needle, but of completely reversing its polarity. By discharging four large Leyden jars through a common sewing needle, he was able to impart to it such a degree of magnetism that, when floated on water, it placed itself in the plane of the magnetic meridian. When the discharge was sent through a steel wire perpendicular to the horizon it was permanently magnetised, with its lower end a North, and its upper end a South pole; and, on reversing the position of the wire and again transmitting through it the discharge, the polarity was either destroyed, or entirely reversed. Franklin also found that the polarity of the loadstone could be destroyed in a similar manner. (Priestley's "History of Electricity," London, 1767, p. 178.)

Dalibard, about the same time, imagined that he had proved that the electric discharge gives a northern polarity to that point of a steel bar at which it enters, and a southern polarity to that at which it makes its exit, while Wilcke, for his part, was equally satisfied that an invariable connection existed between negative electricity and northern polarity.

From a review of all these, and other observations by himself made between 1753 and 1758, Beccaria came to the conclusion that the polarity of a needle magnetised by electricity was invariably determined by the direction in which the electric discharge was made to pass through it; and as a consequence he assumed the polarity acquired by ferruginous bodies which had been struck by lightning as a test of the kind of electricity with which the thunder-cloud was charged.

Extending this criterion to the earth itself, Beccaria conjectured that terrestrial magnetism was, like that of the needle magnetised by Franklin and Dalibard, the mere effect of permanent currents of natural electricity, established and maintained upon its surface by various physical causes; that, as a violent current, like that which attends the exhibition of lightning, produces instantaneous and powerful magnetism in substances capable of receiving that quality, so may a more gentle, regular, and constant circulation of the electric fluid upon the earth impress the same virtue on all such bodies as are capable of it. "Of such fluid, thus ever present," observes Beccaria, "I think that some portion is constantly passing through all bodies situate on the earth, especially those which are metallic and ferruginous; *and I imagine it must be those currents which impress on fire-irons, and other similar things, the power which they are known to acquire of directing themselves according to the magnetic meridian when they are properly balanced.*"*

Diderot, one of the editors of the celebrated "Encyclopædia," and whom the *Revue des deux Mondes*† calls a "Darwinist a century before Darwin," was also, as early as 1762, a firm believer in the identity of electricity and magnetism, and has left in his writings many arguments in support of this hypothesis.

In the year 1774, the following question was proposed by the Electoral Academy of Bavaria as the subject of a prize essay:—"Is there a real and physical analogy between electric and magnetic forces, and, if such analogy exist, in what manner do these forces act upon the animal body?" The essays received on that occasion were collected and published ten years later by Professor Van Swinden, of Franeker—the winner of one of the prizes.‡ Some of the essayists, and amongst them Van Swinden, maintained that "the similarity was but apparent, and did not constitute a real physical resemblance;" while, on the other hand, Professors Steiglehner and Hubner contended that "so close an analogy as that exhibited by the two sciences indicated a single agency acting under different circumstances" (Noad's "Manual of Electricity," p. 641).

In this unsettled state the subject remained for many years until the discovery of galvanism and the invention of the voltaic pile, which, by furnishing the philosopher with the means of maintaining a continuous current of electricity in large quantity, enabled him to study its effects under the most favourable circumstances.

## DEEP SEA CABLES.

The discussion at the Society of Telegraph Engineers the other evening on the subject of submarine cable manufacture, although not very complimentary to the authors, afforded much information which they will not fail to profit by. The discussion was exceptional in several respects. Whether owing to the paper having been longer than usual in the hands of the council, or to their being personally interested in the subject to be considered, their remarks upon it were not only exceptionally prolonged, but were characterised by warmth of expression sometimes bordering on asperity. As the general audience had not enjoyed a previous study of the paper, and were, perhaps, more interested in welcoming a useful suggestion than in defending established practices, they were compelled to listen in silence to a dispute, on the true merits of which they had had no opportunity of forming an opinion. It is a useful innovation to hand a copy of the paper to be read into the hands of the members present. It saves much mental strain, and obviates misunderstanding if the reader happens not to be a trained speaker. But for the purposes of eliciting general discussion it is, perhaps, worse than useless; and experience has shown thus far that it only serves to give the gentlemen round the council table the monopoly of the speaking—they having had the monopoly of a quiet study of the paper in clear type.

Opinions may differ as to the expediency of going one step further, and sending the paper to the members beforehand; but there can be no question that on the occasion to which we are referring the members of council interested in the subject had practically prepared to follow up the paper by individual papers of their own. The President, then Mr. Ford, then Mr. Edward Bright, gave their several experiences with no stint of detail, and we doubt not that Messrs. Trott and Hamilton will benefit by what they heard. They might, however, have profited more, perhaps, if opportunity had been left for other and more disinterested opinions to be offered from the body of the hall. With adverse criticism all innovators must be prepared to do battle, and the authors of the suggestion for superseding iron-sheathed submarine cables by cables preferably covered with hemp will have nerved themselves for such objections as were urged against it last Thursday week. But it is to be feared they will go away with the impression that opposition did not come exactly from the right quarter, and that in fact their suggestion was not discussed on its merits. As we understand it the issue raised was not one as between light cables and heavy cables, concerning which a vast deal of irrelevant talk was indulged in, but as between iron and some other less objectionable material. The authors suggest hemp; but whatever the material it should not be iron. And here was an essential point—it should be wound round the core in a particular way. That way may have been tried before, as was stated; but evidently not with the same object, or its effect watched with a view to ascertaining the merit now claimed for it. We publish Messrs. Trott and Hamilton's paper at length, and it will be seen what is the pricise nature of their recommendation. Except under practical test—which, of course, is a very expensive operation if it happen to fail—no trustworthy assertion can be ventured as to the durability of a cable protected in this fashion; and it happens, too, that it is confessedly more suitable for deep sea cables—in other words, very long cables—than for cables in shallow waters, which renders an experiment all the more hazardous. But the indestructibility of such a cable in deep water, where the animals who dine off submarine cable compounds have not yet been found, is a point soon capable of proof, and its strength as compared with iron-covered cables is a matter of simple demonstration. The chief question, it seems to us, is whether such lightly protected lines would bridge over the chasms known to exist at ocean depths, and the chafing which presumably must occur at the edges on either side.

And here comes in an element in the discussion to which full justice was not done. The authors of the paper are men who have had a vast experience in the picking up of cables; and it is in the picking up, not in their laying down, that information valuable to a discussion on the breakage of submarine cables is acquired. These experts in the picking up of severed or injured cables assert that the causes of their giving way are almost uniformly due to the iron sheathing; first because it corrodes in certain waters and eats into the inner coating; next and chiefly, that it gets a twist when being paid out which results in its either piercing the cable, or, in certain circumstances, breaking on very small provocation. It is obviously a very unyielding material, and the heavier it is the more likely is it to accomplish its own destruction. The fact that cables do not part when being laid is not disputed; what is now alleged on

Digitized by Google

the part of the people who have picked many of them up that have parted subsequently is that they have suffered some injury which could not have been inflicted at the bottom of the sea, but which would be easily accounted for by an initial twist or kink when they were being paid out—a fault to which iron-protected cables are (as these gentlemen believe) peculiarly liable. A collection of careful drawings supplementary to the paper would have been of more use to the authors than any number of quotations from mysterious paragraphs of eminent newspaper correspondents. But in the absence of such evidence the testimony of experience and extended observation is worth a great deal, and Messrs. Trott and Hamilton are just the men who have had special opportunities of accumulating such testimony. A fresh trial for cables without iron armour under conditions more favourable to success than have hitherto been accorded is now invited; and we should be glad if a favourable opportunity arose to put the suggestion to a practical test.

## THE CONSTRUCTION AND EFFECTIVENESS OF ACCUMULATORS.

BY ALBERT BANDSEPT.

At the present time we know the effectiveness of the Faure-Sellon-Volckmar accumulators. The reports of experiments have furnished positive data as to the capacity, the effectiveness, and the cost of these batteries. From the labours and experiments of the specialists most competent to deal with the question it results that the effective return of accumulators does not exceed 45 per cent. of the motive power expended in the first instance; so that the energy transformed by a dynamo machine (receiver) would represent about 30 per cent., which means that it is well established that for 100 horse-power developed initially we can practically obtain but 30 horse-power at the receiving machine, and 44 horse-power of electrical energy from the accumulators.

This return will not astonish those who have taken up the question of accumulators seriously, and it will in no way deter the researches that have been undertaken, more or less everywhere, with the object of increasing the industrial value of these batteries by a rational modification of their construction.

The new type Faure-Sellon-Volckmar cells return about 60 per cent. of the energy available for charging; they absorb and retain 40 per cent. of the work put into them. This loss is a very decided one, and it is worth while to find out to what it must be attributed.

The electro-magnetic portion of this examination has been treated in all its details in the columns of this journal,* and important data as to the nature and formation of supports, as well as their work, have been supplied. It would be well, perhaps, to add some observations on the electro-mechanical portion of the subject by a succinct study of the conditions of working and the construction of plates.

The reason which determined the use of lead from the first is that this metal is admirably suited for the construction of electrodes, because of the insolubility of its sulphate and oxide in dilute sulphuric acid, and also because the oxide is easily produced and is of sufficient conducting power. At the same time account was taken of the great affinity of peroxide of lead for hydrogen; so that the choice which still predominates generally was definitely made at the first. This choice would not have been open to objection if it had confined itself to a combination of lead and peroxide of lead for one of the electrodes only, viz., the positive plate, and if search had been made for a substance strongly electro negative, relatively to hydrogen and to lead, as a support for the second electrode. To this consideration must be added another, which refers to the form of the plates. The system to which the data and facts we are now in possession of refer is that in which no felt is used, with plates perforated with holes, or a grid of cast lead, into which minium, reduced lead, or a salt of lead is compressed. Now, experiment has proved that the use of this kind of support is anything but justified; since, by this arrangement, the electro-mechanical conditions of the system—that is the conductive continuity, and the retention of the material—which are already very uncertain—are still more unfavourably influenced by electro-chemical reactions. During the working of the battery the electrode undergoes certain modifications or changes of form and size, which are able to completely spoil the apparatus, from the moment when plates such as are now employed are made use of. By more or less ingenuity of arrangement things can be so ordered that the plates no longer touch or make short circuits; but it cannot be doubted that the grids warp, and in doing so loosen bits of minium from the smooth-sided apertures which hold them.

Thus, granting on the one hand that, when the minium paste is compressed into the holes in the grid, this paste in hardening and undergoing the alternate effects of contraction and expansion loses its adherence in the holes, and is detached therefrom; that, on the other hand, the perforated plates buckle in the electrolyte—it is easy to

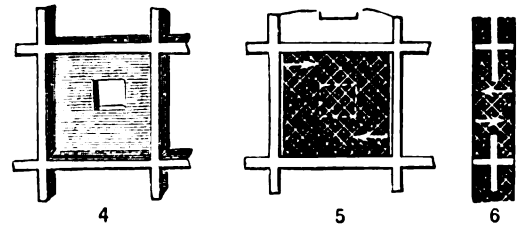
understand how it comes about that the working of this system of accumulators is so uncertain, and why it occasions the loss of so much energy. The inconvenience of receptacles with smoothed-sided holes would not be so remarkable if the plates did not buckle. Endeavours should, therefore, be made to give the supports such a section that the effects of contraction and expansion which the lead undergoes should distribute themselves symmetrically. Banded plates such as separate the cells of the Volckmar plate do not comply with this condition; it would, without doubt, be more reasonable to adopt as a support a series of crossbars, the rigidity of which would be far greater. Leaving out of account the higher value, as far as mechanical resistance goes, of the plate, the crossbar section would afford a different method of retaining the minium, and would prevent it from being detached from its support under any circumstances.



4 represents Empty Cell; 5 Opposite Cells Charged; 6 Double Cell.

*Retention of Minium.*—Here, Figs. 4 to 6, the plug of material is packed in the support.
*Conductive Continuity.*—The withdrawal of the plug carries the material to the common bottom of the double cell.
*Development of Active Surfaces.*—The four sides and twice the bottom surface.

In point of fact, in this case the plug of oxidised material, when it becomes hardened, is virtually encased in the support, because the central core of the latter penetrates into the plug and opposes all movement which tends to separate the minium from the plate. Better still, during the reduction of the active masses, some of these fall to the com-

* Papers by Messrs. C. H. W. Biggs and W. W. Beaumont, and those of Dr. O. Lodge.

Digitized by Google

mon bottom of the two opposed cells, which communicate with each other by a rectangular opening. The adherence between the minium and the lead is therefore increased by this action, and makes up for the loss of continuity which takes place at the circumference of the four sides *a b c d*. The replacing of the receptacle or smooth frame of the Volckmar plate by a true double cell with common bottom would, therefore, have considerable influence, not only from the point of view of the resistance and rigidity of the support, but also as regards the certain retention of minium. Even though the plugs of hardened material were to be shaken in the cells the materials could not fall out, owing to their being encased in the plate; but, further, the mode of working the battery is completely modified, owing to this change in the method of securing the minium, and it is probable that the return, in the two cases, would also differ very sensibly.

In the Faure-Sellon-Volckmar system it is to be feared that the surface of contact between the support and the active materials is not large enough, owing to which a certain quantity of these materials escapes the reducing action of the current. In point of fact each cube of material oxidised is only in communication with the frame which supports it by means of the four sides *a b c d*. Now we have seen that when the battery is working, its materials experience expansion and contraction, as do also the metallic sides between which they are supported, and that owing to these different actions the plugs lose their adherence to the support. There is, therefore, a rupture of conductive continuity between the elements of the electrode—a bad effect, which becomes the more marked the more the plates buckle in the acidulated bath. The result of all these destructive actions is to greatly increase the internal resistance, and to cause the current to very incompletely penetrate the masses which it is required to render active. The immediate result is loss of electro-chemical capacity, and decrease in the return of the battery for a given gross weight of materials.

When M. Faure modified the Planté battery he soon perceived that its capacity did not entirely depend upon the thickness of the layers of materials, as he had at first supposed. He saw that about $\frac{8}{10}$ths of the minium employed remained inert, and uselessly increased the weight of the battery. M. Faure asserted in public communications that the surface of the electrode supports of a secondary battery, whilst exerting great influence on the resistance, had no effect on the absolute return. The inventors of the perforated plate seem to have been of the same mind, for their support for the same given thickness of minium offers no greater development of active surface than the solid plates of their predecessor. For one cube of oxide of 1 centimetre, on 5 mm., for instance, the Faure plate gives as an active surface 2 sq. centimetres, and the Volckmar support, $\cdot 5 \times 4 = 2$ sq. centimetres, the same exactly as the solid plate, covered on both its faces. As regards increasing the active surfaces, the new accumulators have gained nothing, therefore, and the same holds good—as we have just seen—so far as the adherence of the oxide and the lead is concerned. The conditions are changed when the partitioning of the receptacles gives a crossbar section, the vertical bars of which penetrate the plugs of minium. To the above-mentioned development of active surface of 2 sq. centimetres must be added the surface of the central bar, that is to say, 2 sq. centimetres less the hole with a length of $\cdot 5$, or $2 - (2 \times \cdot 5^2) = 1 \cdot 5$; so that the sum of the sides which retain the plug is 3·5 sq. centimetres against 2 centimetres in the preceding case.

We therefore approach far more to the conditions of work in a true cell which should unite the masses to be transformed, and it is for this reason that the industrial value of the apparatus becomes far greater than that which results from the arrangement in open gridframes with straight-sided receptacles.

If, now, we examine the method of canalisation in these supports, we shall readily see that it would be good to accomplish this by means of numerous ramifications extending throughout the materials required to be reduced. On the other hand, it is known that the charging current decreases rapidly when the point of saturation of the battery has been reached, and the two component gases of the electrolyte are disengaged. From this we may conclude that, although the penetration of a smooth plate can be facilitated by a slight oxidation, it is none the less true that the resistance to the circulation of the current becomes the greater as the absorption of oxygen or the transformation of oxide becomes more complete. This transformation, and the penetration of the support and the leaden materials, might be increased, all things being equal, if the charging current was distributed simultaneously at several points of the plate, and not by one entrance only, as is ordinarily done, and in particular as regards the new suspended supports of the Compagnie Métropolitaine.

To sum up, and without insisting on the choice of materials to be employed, we may say that the present system should be completely changed, if the electro-mechanical conditions of the secondary battery are to approach those indicated by theory. Further, there is nothing to prevent recourse being had to such an arrangement of cellular plates that they may be commercially supplied. It would also be easy enough to cast a lead electrode resembling the ideal type of cell. The advantage to be got by a more rational method of construction would take nothing from the simplicity of the process.

## LES TELEPHONES.

AGENCEMENT DES BUREAUX TELEPHONIQUES DANS LES GRANDS CENTRES — APPAREILS — CONSTRUCTION DES LIGNES ET EXPLOITATION—AUDITIONS TELEPHONIQUES MUSICALES FANFARE ADER—AVEC 43 FIGURES GRAVEES DANS LE TEXTE — PAR A. L. TERNANT. MARSEILLE, CHEZ L'AUTEUR, 62, BOULEVARD LONGCHAMP, ET LIBRAIRIE LAFFITTE, 1, BOULEVARD DU MUSEE. 1884.

This pamphlet is a reprint of articles which originally appeared in the pages of the *Bulletin de la Société Scientifique Industrielle de Marseille*. M. Ternant has kindly placed at our disposal the engravings which illustrate his text. We are glad to make use of some of those illustrations, remembering that *The Electrician* is the only publication which has

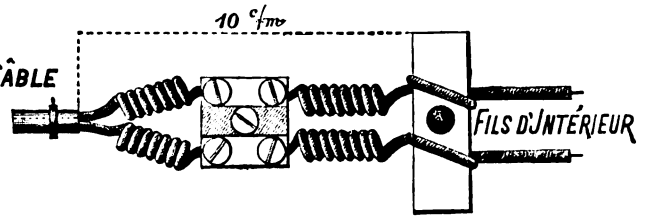

FIG. 1.—Mode of Connecting up a Single Subscriber.

given, or indeed attempted to give, complete practical information relating to the work of telephony. Of history and description we have more than enough—this has been given on every hand. M. Ternant's work contains much information as to the practice in France, and this information will therefore be supplementary to that which has appeared in our columns. We shall indicate the contents of the work, abstracting or translating more fully such parts as may be new to our readers.

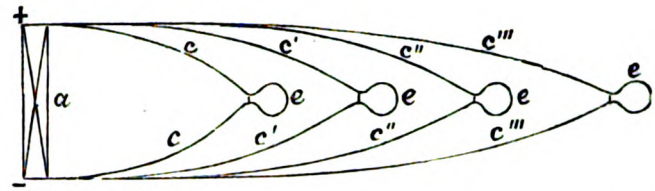
The work commences with a reference to the ideas mooted by M. C. Bourseul in 1854, subsequently realised by Reiss, Bell, and others. This historical *resumé* is followed by a description of the Paris system, the central office of which is at 27, Avenue de l'Opera, with twelve branch offices. The cables used in Paris are manufactured, under the direction of M. Richard, at the works of Besons, the conductor being copper, which is covered with gutta percha and cotton. A number of these conductors are placed together in a lead tube. Fourteen conductors, making seven double wire systems, are thus protected by lead. Each pair of conductors is served

Digitized by Google

with cotton of similar colour, but different from the colour of that of any other pair. The pair of wires of similar colour go to a subscriber. It is thus easy to trace any subscriber's line. Fig. 1 shows the method adopted in connecting the subscriber to the cable. The cables are brought into the central office through a copper sheet pierced with holes and fastened to the wall by pins; thus 250 cables, giving 1,750 circuits, are brought to the office.

Each pair of wires, constituting a subscriber's circuit, are attached to a small commutator, formed of two copper bars, furnished with screws, and insulated from one another on a piece of ebonite. Each cable, comprising seven of these circuits, forms a sector of the *rosace* (the name given to the opening into which the cables are led in the exchange). Fig. 2 shows one of these sectors. Each *rosace* will accommodate 34 of these sectors, which represent 238 subscribers. The small commutators are connected at the other end to insulated wires covered with paraffined cotton, which are led, along the internal circumference of the *rosace*, directly to the commutators, called jack-knives, in the central office. The number of each cable is shown by an ivory ticket. Each of the pairs of wires shows in a similar manner the address of

No drawing is given, but it is not difficult from the above description to produce a diagram.



Let *a* be the generator, *c c' c'' c'''* the leads, and *l l* the lamps. M. Kosloff's invention may fairly be described as a series of lamps in a single parallel circuit. It is important that this should be noted, and also to bear in mind that the patent is void.

No improvement was made on this system for three years, when Mr. Werdermann, in patent 2,477, of 1878, introduced two distinct novelties.

1st. An arrangement by means of which a lamp that was nearest the positive pole of the generator should be furthest from the negative pole, and *vice versâ*.

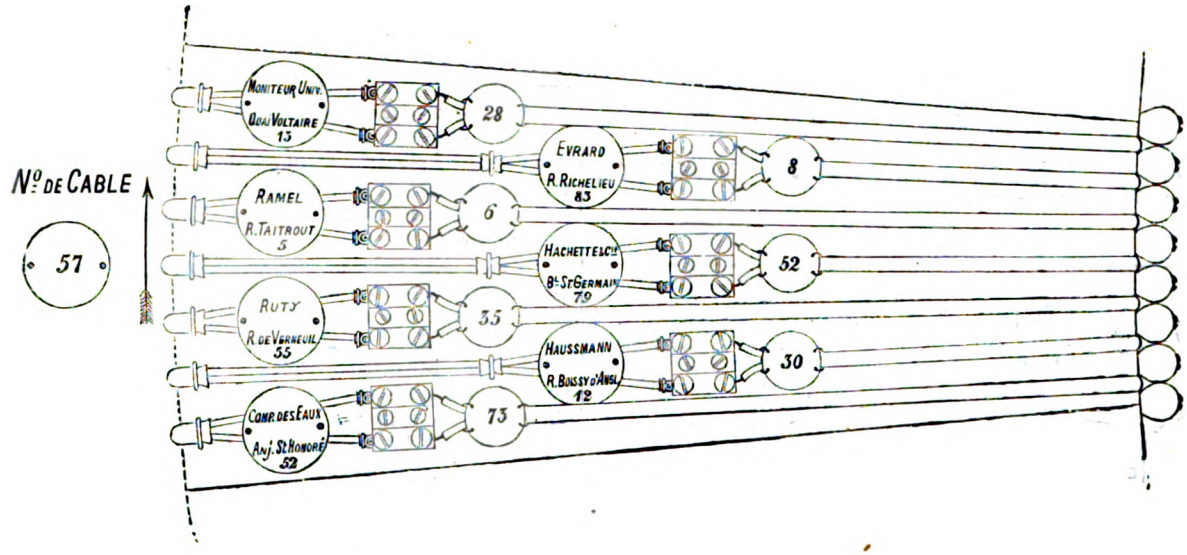


FIG. 2.—A Sector of a *Rosace*, showing the Connections, Subscribers' Names, &c.

the subscriber, and a number corresponding to this is attached to the two ends of the inner wires, which lead, *viâ* the jack-knife, to this subscriber's indicator.

(TO BE CONTINUED.)

## PATENTS FOR DISTRIBUTION OF ELECTRICITY.

BY C. A. STEPHENSON.

The question of the distribution of electricity and its subdivision for the purposes of incandescent lamps is one that has received a good deal of attention from the public, and yet there are not many patents bearing on the subject. The system most generally in use is that of parallel circuits, and I shall therefore give it the priority its importance deserves.

### *Parallel Circuits.*

The first patent for parallel circuits was taken out by a Russian gentleman, M. Alex. Kosloff, No. 2,767, of 1875. As only a preliminary patent was filed it is now void. A method is described of sub-dividing the current of one pole and conducting "the current by separate conductors to each lamp; the current of the other pole sub-divided in the same way meets the current of the first pole in each lamp."

2nd. Branches and sub-branches arranged as above in parallel circuit. The accompanying Figs. 1 and 2, taken from the specification, fully illustrate the whole matter.

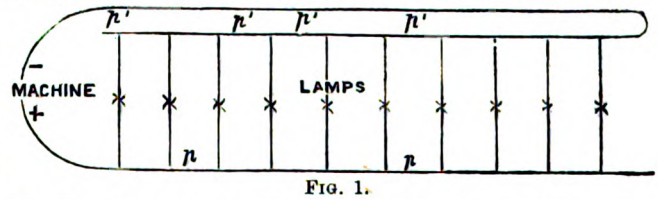

FIG. 1.

In Fig. 1 *p p* are the positive conductors, *p' p'* the negative, *x x* the lamps.

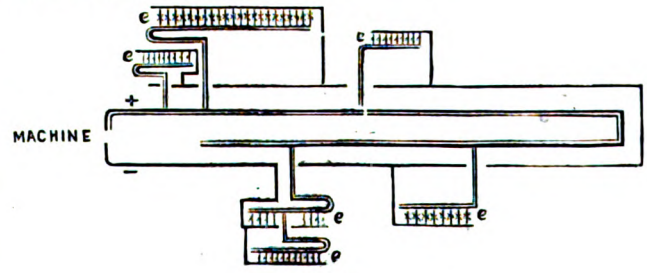

FIG. 2.

In Fig. 2 the positive conductors are shown with double lines, the negative with single, *l l* are the lamps.

Digitized by Google

Mr. Werdermann claims "the apparatus or arrangement comprising the series of parallel circuits in the manner described," &c., but no claim whatever is made for the arrangement by means of which the lamp nearest the positive pole of the generator is furthest from the negative pole. He, then, can only be construed to claim a series of parallel circuits, a single parallel circuit having previously been known.

*Secondary Batteries.*

The use of secondary batteries or some form of accumulator is by no means as new as is generally supposed. The first patent dealing with this question is M. Paul Jablochkoff's, No. 3,839, of 1877. The wording is a little involved. The idea of accumulating a reserve of electricity was certainly not grasped, but Leyden jars, or condensers, were introduced into circuit, as shown in Figs. 3 and 4.

In Fig. 3, A is the generator "giving alternate currents," *b b* are the conductors arranged in parallel circuit, J J are Leyden jars, C a condensor, *l l* the lamps.

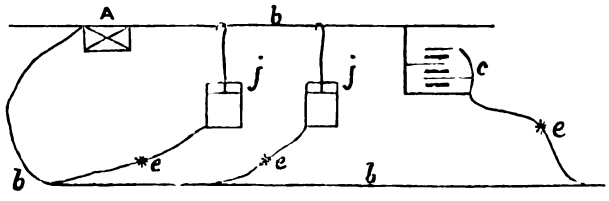

Fig. 3.

Fig. 4 is precisely the same, except that, instead of a parallel circuit, earth is used.

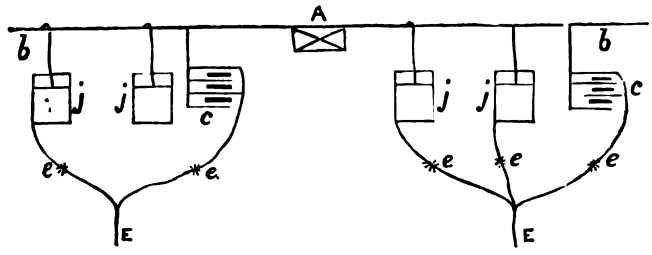

Fig. 4.

The claim made is for the "method of distributing electric currents from a single source of electricity for supplying illuminating apparatus by first converting a current of dynamic-electricity into statical electricity, and then reconverting it into dynamic electricity, which is conveyed to the illuminating apparatus."

The next patent to be noticed is Mr. John Rapieff's, No. 4,432, of 1877. He describes a "combination of dynamo-electric machines, batteries, or generally some circuits bearing the electric current, with so-called polarisation battery and condensator together or separately." How this arrangement is to be carried out is not very clearly described, I shall therefore confine myself to the exact words of the patent. In Fig. 5 the current "is flowing through conductors

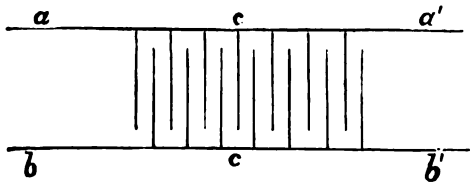

Fig. 5.

*a a' b b'* to the lighting apparatus or to some other destination, and by the way enters without interruption into the polarisation battery or condensator *c c* the current of the conductor *a a'* in one of the sheets of the condensator or pole of the battery *c c*, the current of the conductor *b b'* in the other."

In Fig. 6 "are shown combinations of the same arrangement, the parts *g g* being connected to each other or to earth."

The claim is much in the same strain. It is for "the means of obtaining greater power of light by the use of polarisation batteries or condensators, together with dynamo-electric machines, as hereinbefore mentioned." There can be no doubt on one point. A combination of dynamos, batteries, and lamps is intended, but how to be carried out neither the wording nor the diagrams explain.

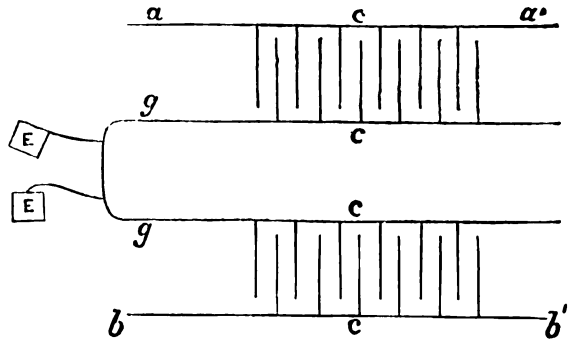

Fig 6.

Up to this time the actual idea of using batteries for storing electricity had not been considered. The notion is due to the inventive genius of Mr. Lane Fox. In patent 3,988 of 1878, after two disclaimers, the claim is reduced to—

"The employment as described of secondary batteries as reservoirs of electricity, in combination with a mode or system of distribution, such as is hereinbefore explained."

Two figures are given, Nos. 7 and 8, and the system is thus described—

"From one pole or electrode of an electric generator or generators (situated at A, Fig. 7) proceed one or more large conductors, from which branch out at various points where lights are desired smaller conductors, which again may have conductors branching off from them, and so on. The other pole or electrode of each electric generator is connected with the earth, so that the conductor and its branches and sub-branches will be perpetually in a state of electric tension tending to develop currents in any direction to earth.

"One pole of the electric lamp is connected with the earth *e*, and this may be conveniently effected by means of gas or

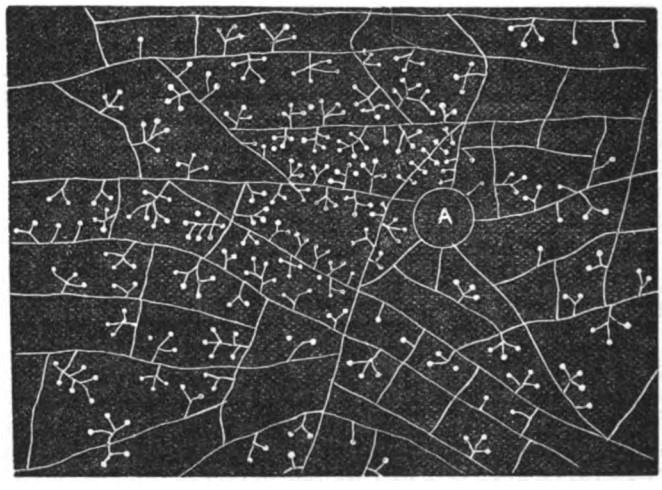

Fig. 7.

water pipes where such exist, so that wherever the circuit is complete between the lamp and any one of these branches a current of electricity will pass through the thin strip or wire, rendering it incandescent, and so produce light.

"A number of secondary batteries such as Planté's (lead and sulphuric acid)—such batteries being joined together in series between the main and the earth—will serve as a kind of reservoir for the electricity. The cells should be of a very large conducting surface, and should have several batteries

Digitized by Google

connected up at various points of the mains, so that by increasing the electromotive force during the hours when not much electricity is being used they will become charged, and the electric force will be stored up in them, so that a sufficient supply will be available when the electromotive force falls, owing to the draft from the mains when the force is most used and needed. The number of cells in each of these batteries will depend on the electromotive force of the mains. Fig. 8 is a diagram representing a secondary battery joined up between the main and the earth for the purpose above described. *e* indicates the earth, and *l* the lamps."

It will be noticed on close observation that the descriptions and the drawings do not quite coincide. In Fig. 7, the ooo being the lamps, one pole should have an earth connection, and several secondary batteries should be inserted at various points of the mains. The description says nothing of the network of leads which join together all the mains and branches.

Fig. 8 shows a single battery joined up in a main, and it will be noticed that the branches are united in a regular network.

The system may be summarised as one of (1) mains, branches, and sub-branches in connection with (2) earth returns and (3) secondary batteries, (4) the mains, branches, and sub-branches being connected in a network.

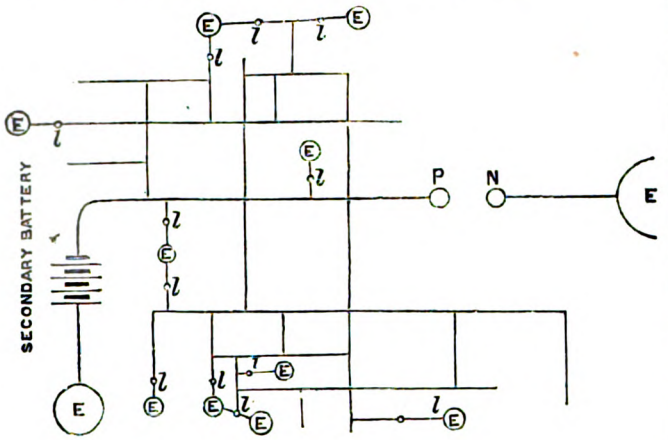

FIG. 8.

Now, as regards mains, branches, &c., this system had already been elaborated by Mr. Werdermann in his patent 2,477 of 1878. The radical difference in the two conducting systems is that Mr. Lane-Fox uses earth instead of metallic returns, and forms a network of the conductors. Mr. Lane-Fox further introduces secondary batteries as reservoirs, and in this he introduces a very distinct novelty, but he limits its use to a combination with earth returns.

Mr. Lane-Fox very soon found objections to the system of charging the batteries by increasing the electromotive force during the hours when not much electricity was being used, and accordingly in patent No. 4,043 (to which one disclaimer has been allowed) he proposes to charge the secondary batteries "by coupling two or more parts of a whole battery for quantity so that they can be charged with a low electromotive force." The claim is for the system consisting of "mains, branches, and sub-branches with returns by 'earth.'"

It is curious how persistently Mr. Lane-Fox has limited his claims to earth returns; the result is that whilst he will in all probability be able to enforce his claim to a patent for using secondary batteries as reservoirs of electricity in a system of distribution with earth returns, he has by publication precluded himself or anybody else from a patent for the use of secondary batteries as reservoirs in a system with metallic returns.

NUMBERS OF "THE ELECTRICIAN" OUT OF PRINT.—The following numbers of *The Electrician* are out of print, and cannot be supplied at the office, viz.:—Vol. 1, Nos. 3, 9, 19; Vol. 7, Nos. 8, 10, 12 to 18, 20, 21, 24 to 26; Vol. 8, 1, 3, 6 to 12, 15 to 26; Vol. 9, Nos. 2, 4, 24, 25; Vol. 10, No. 13.

## ON THE ELECTROMOTIVE FORCE OF ALLOYS.*

BY JOHN TROWBRIDGE AND E. K. STEVENS.

The best study of alloys and the most thorough work on them has been done by Matthiessen, who proved conclusively that alloys were neither mechanical mixtures nor chemical compounds, but what he terms, in a general way, "a solidified solution of one metal in another." He also showed that, with reference to the formation of alloys, metals were divided into two classes—the first class being those which, when alloyed with each other, give a conductivity in proportion to the respective volumes of the two metals; and the second those which, when alloyed with each other, give a conductivity which is less than that of the respective volumes of the two metals.

The aim of this investigation has been to note the variation of electromotive force in different alloys of the same metals, and to deduce, if possible, some general law which governs the variation.

Two sets of alloys were used—one set of lead and tin, and the other of copper and zinc. The first set was made by taking the proportional weights of lead and tin, and melting them together in a crucible, and then pouring them out on a flat surface and allowing them to cool. The second set was made by melting a weighed amount of copper in a Fletcher gas-furnace, and, when in a molten state, adding more than the required amount of zinc, in order to make allowance for volatilisation. Pure metals were obtained, in order that the results might be as accurate as possible.

It was deemed sufficient, as far as the lead and tin alloys were concerned, to weigh out carefully the required amounts of each metal, and to take those weights as showing the composition. This could not be done with the copper and zinc alloys, as it is impossible to determine how much of the zince volatilises; so with these it is necessary to resort to analytical methods of determining the percentage of each. The copper was determined by electrolysis, by precipitating the copper, from a sulphuric acid solution of the alloy, upon a platinum disc connected with the negative pole of a battery, and the positive pole dipping in the solution. The zinc was determined by subtracting the per cent. of copper from a hundred per cent.

The composition of the alloys is given in the tables below, and will be referred to by number hereafter.

| Number. | Alloys of Sn and Pb. | | Number. | Alloys of Cu and Zn | |
|---|---|---|---|---|---|
| | Parts by weight of Sn. | Parts by weight of Pb. | | Per cent. of Cu. | Per cent. of Zn. |
| I. | 1 | 9 | I. | 91·92 | 8·08 |
| II. | 2 | 8 | II. | 85·75 | 14·25 |
| III. | 3 | 7 | III. | 72·99 | 27·01 |
| IV. | 4 | 6 | IV. | 66·70 | 33·30 |
| V. | 5 | 5 | V. | 49·32 | 50·68 |
| VI. | 6 | 4 | VI. | 27·99 | 72·01 |
| VII. | 7 | 3 | | | |
| VIII. | 8 | 2 | | | |
| IX. | 9 | 1 | VII. | 7·53 | 92·47 |

Four determinations were made with these alloys, the first two being the observation of the electromotive force of each alloy, with platinum for the positive pole and the alloy as the negative pole, with fresh pond-water as the liquid; the second two being the determination of the electromotive force with the same positive pole, but with distilled water acidu-

* *Proceedings* of the American Academy of Arts and Sciences, Vol. xviii., May 29, 1883, published in *Philosophical Magazine*.

Digitized by Google

lated with a small quantity of sulphuric acid for a liquid. A mirror-galvanometer and ground-glass scale were used, and a large resistance placed in the circuit, and the galvanometer shunted so as to reduce the deflection.

The first two tables do not give any general law for the electromotive force of alloys, the force being especially irregular, which is, perhaps, due to the fact that the electromotive forces of the two metals are very nearly alike.

The explanation of the third table is rather unsatisfactory, since the sulphate of lead is insoluble, while the sulphate of tin is not known; and this last may account for the change from the first tables. In the fourth table, the increase in electromotive force of the alloys containing the more copper may be accounted for by the fact that the sulphate of copper is more readily soluble than the sulphate of zinc.

I. The electromotive force of the alloys of tin and lead, and of the metals themselves, when the resistance is 7,180 ohms, and the constant of the galvanometer ·000003435.

The first column gives the deflection in millimetres; the second the tangent of one half the angle of deflection; the third the product of the constant by the total resistance; and the fourth the electromotive force in volts. The liquid in this case is water.

| Number. | Deflection. | Tan. ½ angle of deflection. | E.M.F. in volts. |
|---|---|---|---|
| Pb. ..... | 207 | ·0953 | 0·238 |
| I. ..... | 205 | ·0942 | 0·249 |
| II. ..... | 182 | ·0837 | 0·222 |
| III. ..... | 173 | ·0795 | 0·201 |
| IV. ..... | 212 | ·0975 | 0·258 |
| V. ..... | 184 | ·0846 | 0·224 |
| VI. ..... | 216 | ·0993 | 0·263 |
| VII. ..... | 175 | ·0805 | 0·213 |
| VIII. ..... | 208 | ·0956 | 0·253 |
| IX. ..... | 195 | ·0896 | 0·237 |
| Sn ..... | 164 | ·0754 | 0·199 |

II. The electromotive force of the alloys of copper and zinc, with a total resistance of 19,708 ohms, the constant being the same as before, and the liquid fresh pond-water.

| Number. | Deflection. | Tan. ½ angle of deflection. | E.M.F. in volts. |
|---|---|---|---|
| Cu. ..... | 10 | ·0046 | 0·031 |
| I. ..... | 12 | ·0055 | 0·037 |
| II. ..... | 17 | ·0078 | 0·053 |
| III. ..... | 52 | ·0239 | 0·162 |
| IV. ..... | 64 | ·0294 | 0·199 |
| V. ..... | 106 | ·0487 | 0·330 |
| VI. ..... | 131 | ·0602 | 0·408 |
| VII. ..... | 218 | ·1002 | 0·678 |
| Zn ..... | 228 | ·1048 | 0·709 |

The resistance of distilled water is so great, that it was impossible to get any good or satisfactory results. The addition of about one tenth of a cubic centimetre of strong sulphuric acid to about one hundred and fifty cubic centimetres of distilled water gave the liquid used in the last two observations.

III. The electromotive force of the alloys of lead and tin, with total resistance of 22,608 ohms, the constant being the same, and the liquid as stated above.

| Number. | Deflection. | Tan. ½ angle of deflection. | E.M.F. in volts. |
|---|---|---|---|
| Pb ..... | 185 | ·0881 | 0·661 |
| I. ..... | 193 | ·0887 | 0·689 |
| II. ..... | 195 | ·0896 | 0·696 |
| III. ..... | 198 | ·0911 | 0·708 |
| IV. ..... | 197 | ·0906 | 0·704 |
| V. ..... | 196 | ·0902 | 0·701 |
| VI. ..... | 194 | ·0892 | 0·693 |
| VII. ..... | 198 | ·0911 | 0·708 |
| VIII. ..... | 189 | ·0874 | 0·679 |
| IX. ..... | 194 | ·0892 | 0·693 |
| Sn ..... | 202 | ·0929 | 0·722 |

IV. The electromotive force of the alloys of copper and zinc, with a total resistance of 2,380 ohms, and the same constant of galvanometer and the same liquid as in the preceding determination.

| Number. | Deflection. | Tan. ½ angle of deflection. | E.M.F. in volts. |
|---|---|---|---|
| Cu ..... | 43 | ·0188 | 0·153 |
| I. ..... | 34 | ·0156 | 0·130 |
| II. ..... | 40 | ·0184 | 0·150 |
| III. ..... | 43 | ·0188 | 0·153 |
| IV. ..... | 47 | ·0216 | 0·176 |
| V. ..... | 55 | ·0253 | 0·206 |
| VI. ..... | 115 | ·0529 | 0·432 |
| VII. ..... | 203 | ·0939 | 0·768 |
| Zn ..... | 234 | ·1763 | 0·442 |

It would seem to follow, from the last table at least, that in acid solutions the electromotive force of alloys is determined by the proportional part of that metal which is most readily attacked by the acid.

The general differences in the behaviour of the two sets of alloys may perhaps be accounted for by the distinction which Matthiessen* made between the two kinds of alloys. He classes an alloy of lead and tin among those which are "solidified solutions of one metal in another," while he calls alloys like copper and zinc "solidified solutions of one metal in an allotropic modification of another."

## SUBMARINE MINES.

(CONTINUED FROM PAGE 67.)

*The Laflin and Rand Machine.*—This machine, known in the trade as "Magneto No. 3," was patented in March, 1878, and it appears to fulfil more of the conditions desirable for ordinary military service than any of its rivals, while its cost is much less. It has been thoroughly tested at Willetts Point, both on land and in boats, and it is now used almost exclusively when from one to five charges are to be fired. The wooden case is 16in. by 8in. by 5in. in size, the total weight being 18½ pounds. A leathern strap handle, with terminals for leading wires, and a firing bar arranged for external use render the instrument portable and convenient.

The internal arrangement will be understood from Fig. 8. A Siemens armature revolves between soft iron prolongations of the cores of an electro-magnet. The electricity thus gene-

* British Association Report, 1863, p. 47.

Digitized by Google

rated is transformed by a commutator from an alternating to a continuous current. The circuit passes from the commutator springs into the adjacent ends of the windings of the magnet. The back-strap ends of the windings of the two halves of this magnet are extended to the terminals on the leading wires, and thence to a brass spring and collar, where, by platinum contact points, they are joined together, thus completing an interior short circuit tapped by the fuse circuit as a shunt. The magnet is wrapped with 1·76 ohm of cotton-insulated copper wire, No. 18 B.W.G., and the armature with ·92 ohm of No. 21 of the same.

The novelty of the machine lies in the mode of giving rotation to the Siemens armature, and of switching into the fuse circuit the powerful internal current thus induced. Both objects are accomplished by the firing bar, which consists of a square brass rod 14 by ½ by ½in., fitted with a wooden handle at one end. The other end passes down into the box. One side is provided with rack teeth engaging in a loose pinion fitting over the armature spindle prolonged. A clutch holds the pinion to the spindle when the rod is descending, but leaves it free when the latter is raised, thus restricting the revolutions of the armature to one direction only. When the firing bar reaches its lowest position, it strikes the brass spring forming part of the interior circuit 3; and if in rapid motion, the shock breaks this circuit

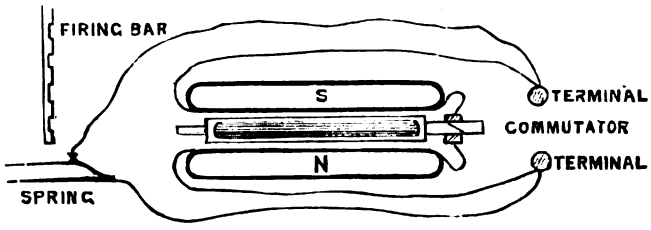

FIG. 8.—The Laflin and Rand Machine.

and thus shunts the current into the fuse circuit. In passing from the top to the bottom of the box the rod causes seven and one-half complete revolutions of the armature; and if the movement be the result of a sudden and downward pressure, this is enough to develop a powerful field of force, and consequently a powerful electrical current.

The nature of the wave generated by this instrument is similar to that developed by the Farmer and the Smith machines; and to determine its effective electromotive force the fuse method of testing described for the former was adopted with the results given in the following table:—

OBSERVATIONS WITH THE LAFLIN AND RAND MACHINE.

| No. of Experiment. | Internal Resistance and Leading Wires. | Fuse at Explosion. | Amount unplugged. | | Measured E. ·5 (R′+R″) |
|---|---|---|---|---|---|
| | | | Failed. | Exploded. | |
| | ohms. | ohms. | ohms. | ohms. | volts. |
| 1 | 2·71 | ·79 | 30 | 28 | 15·75 |
| 2 | 2·71 | ·76 | 33 | 31 | 17·23 |
| 3 | 2·71 | ·77 | 31 | 30 | 16·74 |
| 4 | 2·71 | ·88 | 33 | 31 | 17·25 |
| 5 | 2·71 | ·73 | 28 | 27 | 15·22 |
| 6 | 2·71 | 1·02 | 33 | 31 | 17·36 |
| 7 | 2·71 | ·80 | 30 | 29 | 16·25 |
| 8 | 2·71 | ·86 | 31 | 30 | 16·78 |
| 9 | 2·71 | ·79 | 31 | 30 | 16·75 |
| 10 | 2·71 | ·96 | 30 | 29 | 16·33 |
| 11 | 2·71 | 1·10 | 33 | 31 | 17·40 |
| 12 | 2·71 | ·90 | 32 | 31 | 17·30 |
| 13 | 2·71 | 1·40 | 37 | 35 | 19·55 |
| 14 | 2·71 | ·90 | 33 | 32 | 17·80 |
| 15 | 2.71 | ·90 | 30 | 29 | 16·30 |
| | | Mean ..... | | 30 | 16·93 |

These measurements were made in December, 1879, with a new machine just purchased. They indicate that its effective electromotive force was 16·9 volts. A similar set made with an instrument in July, 1878, gave 12·2 volts. Hence the general working equation for instantaneous action may be regarded:

$$C = \frac{15}{2{\cdot}7 + R''}.$$

Assuming that ·9 ohm is the usual fuse resistance at explosion, and that a minimum current of 1·5 weber is needful to ensure explosion when coupled in series, this equation indicates that eight fuses may be fired on short circuit. Experiment confirms this inference—seven fuses and eight fuses being thus fired successfully, while with 10 in circuit several fail. The instrument, therefore, may be trusted to fire five adjacent guns simultaneously, allowing 2·5 ohms for the resistance of the leading wires. A single fuse may be fired through about 30 ohms. The mechanism is strong, and not likely to get out of order. The only points requiring attention are that no dirt be allowed to collect between the platinum contact points of the break circuit spring; that no metallic dust bridge the cuts in the commutator; and that the spindle bearings, front and rear, be occasionally oiled. By removing a few screws the box may readily be opened for these objects.

*The Ladd Machine.*—This instrument is designed for laboratory use rather than for practical service, and accordingly is not encased. It occupies a space of 22in. by 14in. by 23in. high, and weighs 119 pounds. It was one of the earliest forms of dynamo-electric apparatus, being exhibited at the Paris Exposition of 1867. It consists of a soft iron magnet wound with copper wire of No. 13 B. W. G. The poles nearly envelop a double Siemens armature, composed of two separate armatures abutting end to end on a common axis, the planes of the windings making right angles with each other. The total length of the compound armature is 11in. The separate parts are of unequal length, but both are wound with copper wire of No. 13 B. W. G. The larger or working armature has a resistance of 14 ohms. Two separate commutators are placed at the opposite ends of the axis. The circuit of the smaller armature is permanently restricted to the magnet coils, and its sole work is to create and maintain a strong magnetic field for generating the current in the larger or working armature. The circuit of the latter passes straight from the contact springs of the commutator to terminal binding posts designed to receive the leading wires of the external circuit. The commutator springs of the working armature can be adjusted so as to draw off at pleasure a direct or an alternating current, thus bringing the instrument under Class III. or Class II., as may be desired (*vide* p. 34, *ante*).

The mechanical details of the gearing are novel and ingenious. One turn of the crank gives 155 turns of the compound armature; and a speed of 1,000 revolutions per minute for the latter can easily be maintained.

(TO BE CONTINUED.)

## THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.

At the meeting of this society on Thursday, 29th ult., the following paper, communicated by H. KINGSFORD (associate), on Trott and Kingsford's Automatic Grapnel for Submarine Cables and Torpedo lines, was read by the secretary:—

All those who are acquainted with the cable-lifting branch of submarine telegraphy are well aware how important a matter it is in grappling to be certain of the instant the cable is hooked. This importance increases, of course, with the age and consequent weakness of the material, as the injury caused by dragging a cable along the bottom is obviously very great.

It is easy also to understand the fact that in nearly all cases the most delicate dynamometers must fail to indicate immediately the presence of the cable on the grapnel, more especially in those cases where a considerable amount of slack grapnel rope is paid out. In many cases, therefore, the grapnel will travel through a cable without the slightest indication (or at least

Digitized by Google

reliable indication) occurring on the dynamometer, and perhaps several miles beyond the line of cable will be dragged over, either fruitlessly or to the peril of neighbouring cables ; whereas, should the engineer be advised of the cable's presence on the grapnel, the break will probably be avoided and the cable lifted ; at any rate the position of the cable will be an assured thing.

My own knowledge of cable grappling has convinced me of these facts ; and I am well assured that those engineers at least who have been engaged in grappling for cables in great depths, or for weak cables in shallow water, will heartily agree with me.

In addition to the foregoing remarks *re* the insufficiency of the dynamometer as an instrument for indicating the presence of a cable on the grapnel, I might remind engineers of the troubles and perplexities which occur incessantly in dragging over a rocky bottom. The grapnel hooks a rock, a large increase of strain is indicated on the dynamometer, and it becomes doubtful whether the cable as well is hooked or not. Again, it frequently happens in grappling over a rocky bottom that one or more prongs are broken off, the grapnel thus becoming useless, great waste of time being thus occasioned. Fully realising all the difficulties herein enumerated, it occurred to me that a grapnel might be constructed in such a manner as to automatically signal by electrical means the hooking of the cable, while it would ignore all strain that external causes might bring to bear on it, and thereby obviate the uncertainties attached to the use of the grapnels at present in vogue. To effect this, I designed early in 1881 a grapnel fitted in each prong with an insulated conducting surface, and a plunger and pin so arranged that the cable, when hooked, should by the pressure that it would bring to bear on any of the plungers, cause the pin to come in contact with the conducting surface, itself in electrical communication with any suitable current detector and battery on board the repairing ship, and thereby complete the circuit. This grapnel was successfully used on the Anglo-American Telegraph Company's repairing steamer "Minia" in the summer of 1881, and a patent, No. 13,665, was granted me in Canada for the same on November 10th of that year.

Subsequently, in discussing the construction of the grapnel with Captain Trott, we concluded that something was yet wanted to render the successful working in deep water absolutely sure, and we decided, consequently, to make certain alterations, and to secure the improved form of apparatus in England, France, the United States, and Canada. These patents have been granted, and patents have been applied for also in Germany and Belgium.

This improved form may be constructed either with a contact-plate in each prong or with one contact-plate common to all the prongs ; the latter is somewhat simpler, and is therefore the plan that we usually adopt. Both forms are shown in the accompanying diagrams. The form of grapnel in diagram No. 1 has one advantage over the other in this respect, viz., that should a prong be ruptured so as to render it useless, the fact would immediately be known on board. A circuit formed in such a manner, by the breaking off of a branch lead, would have greater resistance than that formed by the contact resulting from pressure of cable on the plungers. This difference would be manifested on the indicator (of low resistance) placed in circuit with the alarm-bell, or, if any doubt remained, Wheatstone's bridge, or, simpler still, a telephone might be made use of.

In some cases we may protect the plungers from the pressure of ooze, &c., by guards fitted to the stem of the grapnel, but in practice we have not found these to be necessary.

The water is allowed free access around and about each separate part, in order that its pressure shall be equal on all sides. This arrangement renders the grapnel as effectual in the deepest as in the shallowest water.

By making the plungers in two pieces, with a rubber washer or its equivalent between them, we prevent mud or ooze from getting behind and interfering with their working.

As the hole in the rubber surrounding the contact-plate, caused by the passage of the pin through it, closes up as soon as the pressure is removed, leaving in the rubber a fault of exceedingly high resistance, the rubber does not require renewing.

In the rubber in which we embed the contact-plate we place a layer or more of tinfoil, or other easily-pierced conducting surface, through which the pin passes on its way to the contact-plate proper. This method we have adopted in order to make the assurance of contact doubly sure.

The grapnel just described we have had in use on the "Minia" since April last. We have tried it severely, and have never known it to fail. No swivel has been used with the rope, in the heart of which is the insulated wire, as it would allow the grapnel to turn over on the bottom, and would be apt to twist and break the wire short off. As a matter of fact the grapnel will turn, and does turn, with the rope ; a swivel is therefore of no value. We are perfectly awake, however, to the fact that a grappling-rope should be made in a manner that will not allow it to kink, and engineers should avail themselves of such rope, especially in deep water. Patents have lately been granted to Messrs. Trot and Hamilton for the invention of a form of rope or cable answering all the requirements of this work.

A small type of grapnel fitted in the manner I have described may be very advantageously used for searching purposes, to ascertain the position either of telegraph or torpedo lines ; by towing at a quick rate much time may be saved. The position being ascertained, if it be not desired to lift the cable, the grapnel can be released and hove on board by a tripping line, which can always be attached when such work is contemplated. The great importance of being able to localise an enemy's torpedo lines without raising an alarm will be readily seen by engineers engaged in torpedo work.

The reading of the above paper was followed by one on Submarine Telegraph Cables, their Decay and Renewal, by Messrs. Samuel Trott and Frederic Adam Hamilton (associates).

When we consider the enormous extension of ocean telegraphy during the last few years, it is somewhat surprising that so little information has been imparted concerning the condition of cables after various periods of submersion ; and as the subject is both interesting and important, we propose submitting to the society the result of some of our own experience in connection with the submerging and repairing of submarine lines.

As some ocean cables have now been submerged for considerable periods, and very large sums have to be expended in keeping them alive, we will offer a few remarks on some of the causes of rupture and decay to which these costly properties are liable, and state our views with regard to the measures that should be adopted in order to reduce these serious casualties to a minimum.

It is unnecessary to explain in this paper how submarine cables are manufactured, and of what materials they are composed, seeing that we are all so familiar with, or at any rate have access to, publications bearing on the subject. It is sufficient for us to observe that the leading characteristics with regard to the form or type of cable adopted in the earliest period in the history of submarine telegraphy have been rigidly adhered to up to the present time.

We intend to confine our remarks in this paper to Atlantic cables—first, because they are the most important, and secondly, on account of their being the ones with which we are most familiar.

The principal accidents to which these cables are liable may be briefly enumerated, as follows :—Abrasion by ice and on rocky and stony bottom ; ruptures caused by vessels' anchors ; injuries inflicted by marine insects ; *and the wringing asunder of the core by the iron wires.*

Accidents arising from the first cause have not been numerous ; indeed, taking into consideration the heavy masses of ice that beset the coasts and banks of Newfoundland and Cape Breton Island, and extend far west along the shores of Nova Scotia, it is marvellous that so few cases of crushing have occurred.

With regard to breaks on rocky and stony bottom, it is worthy

Digitized by Google

of remark that, excepting in the case of those which have taken place in the immediate vicinity of the shore or in very shallow water, few can be recorded; and we may here state, as the result of long and careful observation, that cables are rarely chafed through, and we believe that injuries attributed to this agency should in some instances be put down to quite another cause.

The number of breaks which have occured to some cables, in consequence of fishing vessels hooking them with their anchors, is greatly in excess of those brought about by any other means; but as these accidents are to a great extent unavoidable, and are easily and rapidly repaired, we will dismiss this portion of our subject with the remark that, considering the number of vessels engaged in the great fisheries on the banks lying between the meridians of 48deg. and 70deg. west, the wonder is that the cables are not broken far more frequently.

In reference to faults caused by marine insects, it can be said that, although the Atlantic cables have not enjoyed a complete immunity, they have been remarkably free from any very serious attacks of these borers, and as their assaults can be repelled by well-known means we do not consider the question a very prominent one as far as Atlantic cables are concerned.

We now have to consider the most serious of all accidents to which submarine cables are liable during the process of submersion whilst being hove in, and after having been successfully deposited in the depths of the ocean.

All who are familiar with the history of Atlantic cables will remember the very interesting account of the early efforts made to connect the two continents, and how, in spite of difficulties which we will not stop to discuss, these efforts were crowned with success.*

A careful perusal of this detailed account—one of the few concerning such undertakings—will suggest the inquiry: How is it that cables suddenly sever during the process of laying or whilst being picked up, without any abnormal strain being indicated or applied? And why do they, in an equally mysterious manner, break in deep water, after having been successfully submerged?

In the work to which we have alluded, such remarks as the following are of frequent occurrence:—"When suddenly the continuity of the electric current ceased, and the electricians declared that the cable had broken at the bottom. . . . . It snapped close to the ship. . . . . The electricians on board reported that continuity had ceased. . . . . When suddenly it snapped, *without any perceptible cause*, under a strain of only 2,200 pounds. . . . . The strain *one-third less than breaking strain*, everything favourable, and yet the cable parted, *silently and suddenly*." Speaking of one disaster in particular, Dr. Russell says:—"The two other breaks might be accounted for and guarded against for the future, but there was something in the latter not so easy of explanation, *and which seemed to point to some mysterious agency existing in the depths of the ocean, beyond the perception of science or man's control.*"

The agency described as *mysterious* still exists, and the history of some of the most recent Atlantic cables, if published, would prove that these so-called improved types are liable to the same mishaps as those we have mentioned; indeed, they are even more liable, for notwithstanding their strength, it is quite as difficult, and even more so, to recover them from deep water.

It is greatly to be regretted that records such as Dr. Russell's have not been published respecting other and more recent cable expeditions.

After years of experience in submarine telegraphy, we naturally arrive at conclusions different to those held by some of our predecessors and contemporaries; and although we have no right to attack the past or the present, we are perfectly justified in reviewing both. We should certainly be wanting in ordinary perception if we failed to read between the lines when studying some of our records concerning Atlantic cables.

When we consider the misfortunes which have attended some of the more recent operations in the Atlantic, we feel that the time has come when the question as to the reason for such expensive and disastrous results should be fully discussed. This brings us to the question: Why do cables suddenly sever in deep water whilst being submerged or when being picked up, and even after being successfully submerged?

Iron-armoured cables have a strong tendency to twist or curl, as the spiral *lay* of the wires imparts a constant helical force in a direction contrary to the *lay*.

Consequently, any slack given is apt to result in a kink or a succession of kinks, which is followed by a wringing asunder of the fabric when the strain is renewed. This accounts for most of the misfortunes which have happened in submerging some cables, for whenever it became necessary to stop or slacken speed in shifting from one tank to another, or for some other purpose, the risk of this accident has always been incurred.

An iron-armoured cable cannot be recovered from deep water excepting in short lengths, because the operation of heaving in causes the armour to unlay or untwist, and this results in an accumulation of turns at and near the ocean bed, and a wringing or wrenching asunder of the fabric is sure to occur.

Cables sometimes break in deep water, because when the iron wires become weakened by corrosion the curling or untwisting tendency is unopposed, and the stronger portions on either side of the weakened spot untwist, thus exerting a force contrary in direction on each side, but concentrated in action at the damaged portion.

This is the whole secret—this is the *mysterious agency*, and thus it is that the most serious cause of injury to submarine cables must be attributed to the iron wires.

We think we have shown that iron wires for deep sea cables are not only undesirable, but deleterious. That this so-called protective material has caused the loss of the 1865 and 1866 cables we have conclusive evidence to show; and it may reasonably be assumed that the same destructive agency which we have described is still at work, so that it becomes an imperative necessity to endeavour to provide a remedy, or at least to try to mitigate in some degree the evils arising from the cause named.

The following opinions will, we think, be taken in evidence in support of our statements respecting the '65 and '66 Atlantic cables:—

At the half-yearly meeting of the Anglo-American Telegraph Company, held February 7, 1879, Lord Monck said: "The failure of the 1866 cable was caused by oxidation of the iron wires and decay of the hemp."*

Mr. W. H. Preece, in a Cantor lecture, delivered April 28, 1879, said: "Submarine cables are really practically of only one type. . . . The form of the Atlantic cable of '65 and '66, which is similar to that of many other cables, was deficient, inasmuch as, while it possessed sufficient strength to enable it to be submerged, it had not sufficient durability to retain that strength to enable it to be brought to the surface again in a sufficient length to enable them to effect repairs. . . . Sometimes the cables rest on corrosive stones, copper ores, and ironstone, when corrosion sets in and causes the cables to speedily fail."

The following communication in regard to the abandonment of the effort to recover and repair the 1866 Atlantic cable appeared in the London morning papers of July 28th, 1878:—

"The steamships 'Seine' and 'Calabria,' which were sent out by this company at the end of May for the recovery and repair of the 1866 cable, returned to London this morning. The cable has been hooked several times, and partially raised to the surface; but the outside iron wires were so weak from the effects of oxidation, that its repair was considered impracticable by the engineers in charge of the expedition.

"(Signed) Henry Weaver,
"General Manager.

"Anglo-American Telegraph Company (Limited),
26, Old Broad-street, London, E.C."

Mr. John Pender, M.P., stated, December 4th, 1878, "that it had been proved that the sea, instead of destroying the gutta percha, had the opposite effect; *it was only the iron wires that were affected.*"

Sir William Thomson has also stated "that the presence of carbonic acid in water is the great cause of iron being corroded."†

We could continue to produce evidence of this description, and we have no doubt that there are some belonging to this society who are able to endorse the statements already advanced, viz., that gutta percha is practically indestructible, but iron wire has caused the loss of many miles of submarine cables, and that, excepting when in contact with iron, vegetable fibre is indestructible.

We could cite numerous instances of cables having been lifted from considerable depths solely by means of the yarn portion of the fabric, which retained its strength sufficiently to bear the superincumbent weight of oxidised iron wires. The core serving, which is composed of common jute yarn, has time after time done duty as the strength-giving material, although only intended as a padding for the iron armour. This core serving is invariably recovered in a wonderful state of preservation, but the yarns which envelop the iron wires suffer deterioration whenever the latter become oxidised.

The testimony with regard to the enduring qualities of vegetable fibrous material is, in our opinion, so overwhelming that we are justified in believing it will be readily admitted that a cable constructed without iron wires, and with the strength-giving material composed of hemp, will not possess within itself the elements of decay.

* "The Atlantic Telegraph," by W. H. Russell, LL.D.

* Hemp is practically indestructible, excepting when in contact with iron

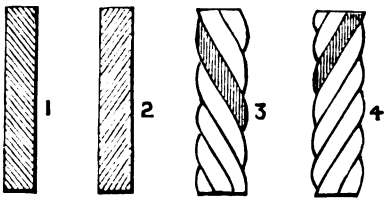
In the case of close-armoured cables covered with an outside serving carrying bituminous compound, oxidation is certainly retarded, but on some bottoms this is only the case to a very slight extent, so that it must be admitted that, wherever corrosion sets in and destroys the iron wires, they have proved themselves a source of weakness instead of strength; for where repairs are effected to cables in which the iron wires are useless, and the yarn portion is the means by which the repair is accomplished, it is plain that the iron is only an encumbrance. If the iron armour has to be protected by means of vegetable fibre and bituminous compound, why cannot a less perishable material be more effectually protected with the same coatings?

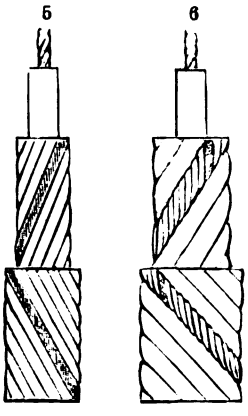
Whenever close-armoured cables suffer corrosion, the wringing asunder of the core is more likely to occur than it is in the case of a strand cable; for if the corrosive action is confined, as is often the case, to one particular spot, on either side of which there is a considerable length unattacked, the untwisting of the armour at the weak place exerts a more powerful force than that which would follow under similar conditions on a strand cable.



If the deterioration were general for any considerable length, there would be less danger of rupture, for then the turns resulting from the untwisting would be distributed.

We are aware that various types of light cables have been devised, and that the question has been discussed from time to time by the members of this society and by others; but the subject has been allowed to drop, partly on account of the fact that some unsatisfactory feature has rendered the adoption of the suggested type undesirable, and partly because of the very strong feeling which exists in favour of heavy armour; and we must say that, were it not that our convictions compel us to arrive at conclusions in favour of the entire abolition of the use of iron wire for the deep-sea portion of an Atlantic cable, we should hesitate before venturing to do otherwise than accept the opinions advanced in support of the use of such material.

We are convinced that a renewal of this question cannot fail to prove beneficial to the cable companies and the public generally; and we are sure it will meet with that consideration on the part of this society so important a subject demands.



We will now proceed to state what, in our opinion, is the most suitable type of cable for the deep Atlantic.

The strength-giving material, by means of which the core can be submerged and recovered, should consist of fibrous yarns or strands made up in such a manner that any twisting or wringing of the fabric is prevented; and, in order to accomplish this, we lay over the insulated conductor a series of spiral or helical servings of non-metallic fibres, yarns, or cords, laid alternately left and right, *the fibres, yarns, or cords of each serving being twisted in a direction the reverse of that in which they are wound about the insulated conductor.*

This point or feature, although at first sight a trifling consideration, is of the utmost importance, as it constitutes the gist and substance of the principle by means of which any twisting or knuckling of the cable is prevented; for it will be seen that, if the yarns or cords of each serving be similar—that is to say, if they be twisted in the same direction in forming them—the cable will kink, notwithstanding the servings be wound alternately in right and left hand spirals about the core.

In the accompanying diagrams, Figs. 1, 2, 3, and 4 represent the yarns and cords with which the insulated conductor may be served, and Figs. 5 and 6 represent completed cables made up of such yarns and cords.

In the case of a cable constructed as shown in Fig. 5, it is obvious that the natural tendency of the first layer or serving to untwist will have the effect of twisting up, and consequently hardening, the yarns composing such layer, as the yarns are laid on in the opposite direction to that in which they are twisted.

So, likewise, the following layer or serving, being composed of yarns twisted oppositely to those of the first layer, and wound around in a reverse direction, will not only oppose any untwisting tendency of the preceding layer, but be hardened and consolidated in like manner, and the whole fabric will be compensating in character—that is to say, the outer layer will prevent the inner layer from causing any kinking or knuckling, and the like effect will be produced on the part of the inner layer.

The same result will, it is obvious, be produced by means of the cords shown in Figs. 3 and 4, when laid on in the manner illustrated in Fig. 6; and it is also equally plain that the laying on of the spirals may begin either to the right or to the left, the essential point in this regard being that succeeding spirals shall reverse their direction.

The servings may be coated, saturated, or filled with tar, bitumen, asphalte, or other preservative material, and may be wrapped with yarn or tape.

A cable such as we have described would not only be more durable than an iron-armoured one, but could be recovered with ease and certainty from any depth.

Strength, lightness, and durability are, we affirm, among the chief requirements in a submarine cable, and these qualifications are to be found in the type which we now submit to the consideration of this society. We have reduced this paper to the smallest possible limits, but trust that our remarks will give rise to a thorough investigation, and that we shall have the opportunity of studying the views of others before going further into details.

A lengthened discussion on these papers ensued, in which the president (Mr. Willoughby Smith), Mr. Ford, Mr. Edward Bright, Mr. Crampton, and Mr. W. H. Preece took part, the last-named gentleman defending the authors of the latter paper from what he considered the somewhat ungenerous criticism of the other four gentlemen, who had apparently not quite understood the real drift of the author's propositions. These were further explained by the authors themselves, and the meeting terminated at an unusually late hour with the usual vote of thanks.

## ELECTRICAL CONDUCTORS.*

The author stated that the first aerial conductors were made of copper, and the first gutta percha-covered wires were of iron; but the positions were soon changed, copper being universally used for insulated conductors, and iron, until lately, for overhead lines. Sir William Thomson detected great variations in the quality of copper, and Matthiessen detected the causes, and established a standard of purity. Such improvements had been made in the quality, that copper wire was now twice as good as it was in 1856. Increased speed of working, improved efficiency of apparatus, and reduced waste of energy had followed the great increase in the purity of the copper. Temperature was a disturbing agent in the conductivity of the wire. Resistance increased more than 20 per cent. between winter and summer temperatures. Copper had recently been much used for aerial lines, it was less attacked by acids, and had great durability. Hard-drawn wire was now produced which had a breaking strain of 28 tons on the square inch, iron wire giving only 22 tons on the same area. Age did not seem to affect its quality, nor did it appear to be influenced by the currents of electricity employed for telegraphic purposes. The conductors of all cables remained constant. Lightning was supposed to render it brittle. The ultimate effect of the powerful currents employed for electric lighting was not yet known. The size of conductors was controlled by commercial considerations. Sir William Thomson had laid down the law that should control the size of leads for electric light, while that for cables followed strictly theoretical conditions. The best copper for electrical purposes came from Japan, Chili, Australia, and from Lake Superior; but much pure copper was obtained by electro-deposition, either directly from a solution, or by using impure copper as the anode in a depositing bath. Electro-deposited copper had not the strength of ordinarily refined copper. The electrical resistance of commercial iron was from six to seven times that of copper, but its variation,

* Abstract of paper read before the Institution of Civil Engineers, on the 4th inst., by Mr. W. H. Preece, F.R.S., M. Inst. C.E.

Digitized by Google

due to the presence of impurities, was even greater. The weight of a cylindrical wire one mile in length and giving one ohm resistance at 60° Fahr. was called an ohm-mile. While the first iron wire was specified to give an ohm-mile of 5,500lb., it was now obtained as low as 4,520lb., and the maximum resistance was specified at 4,800lb. The ordinary best puddled iron was at present used only for fencing purposes, but a mild English Bessemer steel was largely used for railway telegraphs and for stays; however, the resistance was very high, owing to the presence of manganese.

The wire used by the Post Office was made from Swedish charcoal iron, with an ohm mile resistance, of about 4,520lb. Swedish Bessemer, or a specially prepared low carbon English Bessemer, was adopted by the Indian Government, with an ohm-mile resistance of about 5,000lb. Cast-steel wire, with a breaking-weight of about 80 tons to the square inch, had been adopted on the Continent for telephone currents, with an ohm-mile resistance of 8,000lb., while in England, where speed of working was the prime consideration, and length of span was negligible, electricians were satisfied with a breaking strain of 22 tons on the square inch; in the colonies, where long spans were essential, and speed of working was not so important, the specification was 30 tons on the square inch.

The electrical conductivity of iron wire increased with the percentage of pure iron, except where the percentage of manganese was high; an increase in the percentage of manganese augmented the electrical resistance considerably more than an increase in the percentage of sulphur or phosphorus. The durability of iron wire was maintained by galvanising. When the galvanised wire was to be suspended in smoky districts it was additionally protected by a braided covering, well tarred. In some countries galvanising was not resorted to, but dependence was placed on simple oiling with boiled linseed oil. Such a wire was erected in 1856 between London and Crewe, but the result was very unsatisfactory. More recently (1881) the experiment had been repeated with a similar result. In this climate galvanisation was imperative.

But it was not alone in smoky districts that iron wire decayed. It suffered much along the seashore. The salt spray decomposed the zinc oxide into soluble compounds, which were washed away and left the iron exposed, and this was speedily reduced to mere thin red lines.

Where external decay was not evident, time seemed to have no apparent effect on iron wire. Thirty-nine years of incessant service in conveying currents for telegraphy had not apparently altered the molecular structure of the iron wires in the open country on the London and South Western Railway.

Swedish charcoal-iron was imported either in bloom or in rods, principally in rods. Each rod was rolled down to about 0·26in. in diameter, and weighed on the average about 1 cwt. Iron wire could be rolled and drawn into coils 0·171in. in diameter, weighing 400lb., and measuring 1 mile; but 110lb. was about the best practical limit for transport and use. The Swedish iron owed its value not only to its comparative purity, but to the fact that it was smelted and puddled entirely with charcoal. The best qualities were a mixture of various ores, and they were known by various brands, the conditions determining those brands being secrets.

The operation of testing was a most important one, and requisite not only for the user, but also for the manufacturer. Flaws, impurities, faults, notwithstanding the greatest care, would occur, and they could be detected only by the most rigid examination and tests. Tests were mechanical and electrical. The mechanical tests embraced one for breaking strain, another for elongation, and a third for resistance to torsion. For hard steel wire, in place of the torsion test, it was usual to specify that the wire should bear wrapping round its own diameter and unwrapping again without breaking. The electrical test was simply that for resistance—$\frac{1}{30}$ of a mile of the wire to be examined was wound round a dry wooden drum, and its electrical resistance was taken in ohms by means of a Wheatstone bridge. Galvanisation was tested by dipping in sulphate of copper, and by bending or rolling round a bar of varying diameter, according to the size of the wire. Special machines were constructed for the mechanical tests, the condition to be fulfilled being that for the breaking-strain the increasing load or stress should be applied uniformly, without jerks or jumps, and the elongation machine should correctly register the actual stretch without the wire slipping. The resistance to torsion of the wire was determined by an ink mark which formed a spiral on the wire during torsion the number of spires indicating the number of twists taken before breaking.

The perfection to which the manufacture of iron wire had been brought was very much due to the care bestowed upon the specifications by the authorities of the Post Office. The standard had been gradually raised, until it had attained a very high one.

Many administrations objected to the expense of thorough inspection, with the result that they were the recipients of the rejected material of those who did rigidly inspect. One break in the wire cost far more than its inspection, and one extra ohm per mile affected the earning capacity of the wire in inverse proportion. It was, however, necessary to remark that the mechanical quality of charcoal-iron wire sometimes changed with time—its electrical quality remaining unaffected. Tests repeated at some subsequent period might therefore be deceptive unless allowance were made for the effect of time. Bessemer or homogeneous iron wire as a rule improved in its mechanical properties by being kept in stock.

The Post Office authorities had decided to abandon a gauge altogether as applied to conductors, and to define size by diameter and weight. In future, all copper wires would be known by their diameters in "mils." or thousandths of an inch, and all iron wires by their weight in lbs. per mile.

Steel wire was used for long spans, or for places where great tensile strength was needed; but it was for the external strengthening of deep-sea cables that steel wire was principally adopted. It was first employed in the Atlantic cable of 1865 for this purpose. It had since been generally used for deep sea cables. The usual diameter was 0·099m., and it was specified to bear a breaking strain of 1,400lb., which was equivalent to eighty-one tons on the square inch. Steel wire had been produced giving a much higher tensile strength. A compound wire of steel and copper was introduced in America about 1874, and it had been extensively tried in both hemispheres, but without success. Recently a compound wire had been erected between New York and Chicago, a distance of 1,000 miles, giving only 1·7 ohm resistance per mile. It had a steel core 0·125in. in diameter and was coated with copper electrolytically to a diameter of 0·25in. It weighed 700lb. per mile. Hard drawn copper, or silicious bronze of a much lighter character would be equally efficient.

Phosphor-bronze, the hard mechanical qualities and great resisting powers of which were well-known, was introduced for telegraph wire about five years ago. Several lengths were erected by the Post Office. Two long spans crossed the channel that separated the Mumbles Lighthouse from the headland near Swansea. The object in view was to obtain great tensile-strength with a power to resist oxidation, especially active where the wire was exposed to sea spray. This was done in 1879, and in November, 1883, not the slightest change was noticeable in the wire. But phosphor-bronze, though extensively used, had high electrical resistance; its conductivity was only 20 per cent. that of copper. Moreover, the phosphor-bronze supplied was irregular in dimensions and brittle in character. It would not bear bends or kinks. A new alloy, silicious-bronze, had recently been introduced to remedy these disadvantages. Phosphor-bronze had disappeared for telegraph wire, and had been replaced by silicious-bronze. The electric resistance of silicious-bronze could be made nearly equal to that of copper, but its mechanical strength diminished as its conductivity increased. Wire whose resistance equalled 90 per cent. of pure copper gave a tensile-strength of 28 tons on the square inch; but when its conductivity was 34 per cent. of pure copper, its strength was fifty tons on the square inch. Its lightness, combined with its mechanical strength, its high conductivity and indestructibility, rendered it eminently adapted for telegraphs. If overhead wires were erected of such a material, upon sightly supports, and with some method, there would be an end to the meaningless crusade now made in some quarters against aerial lines. These, if constructed judiciously, and under proper control, were far more efficient than underground lines. Corporations and local authorities should control the erection rather than force administrations to needless expense and to reduced efficiency by putting them underground. Not only did light wires hold less snow and less wind, but they produced less electrical disturbance, they could be rendered noiseless, and they allowed existing supports to carry a much greater number of wires.

German silver was employed generally for rheostats, resistance coils, and other parts of apparatus in which high resistance was required. It consisted of copper four parts, nickel two parts, and zinc one part. It possessed great permanence, and the variation in its resistance due to changes of temperature was small. The effect of age on German-silver was to make it brittle. Mr. Willoughby Smith had found a similar change with age even with wire drawn from an alloy of gold and silver.

The form and character of electrical conductors must vary with the purposes for which they were intended. For submarine cables and for electric-light mains, where mechanical strength was not required, and where dimensions were of the utmost consequence, the conductors must be constructed of the purest copper producible, for copper was the best practical material at command. For aerial lines they must not only have great tensile-strength, but in these days of high-speed apparatus they must have high conductivity, low electrostatic capacity, expose to wind and snow the least possible surface, and must be

Digitized by Google

practically indestructible. Iron had hitherto occupied the field, but copper and alloys of copper seemed destined in many instances to supplant that metal, and to fulfil all the conditions required in a more efficient way, and at no greater cost per mile.

## FAURE ELECTRIC ACCUMULATOR COMPANY (LIMITED).

The adjourned ordinary general meeting of this Company was held on Thursday, the 6th inst., at the Terminus Hotel, Cannon-street. The chair was taken by M. E. H. Cadiot.

The Secretary read the notice calling the meeting.

The CHAIRMAN stated that that was the third time he had appeared before them at an adjourned meeting, and he regretted that he had to make the same statement as before. The directors of course knew that this would cause disappointment among the shareholders, but he could assure them most positively that they were doing their very best to bring the matter to a successful termination. Events had been against them, but as he had said before, and now repeated—they had every hope of success. The directors, he assured them, were perfectly blameless in the matter. At the last meeting he held out hopes of the success of the sale of the shares of the French Metropolitan General Electric Company by the French group of financiers in Paris who had undertaken this operation. It had turned out that difficulties had been thrown in their way, and, as it was believed, by enemies. The result of the issue of the shares of the French Metropolitan Company by the financial group referred to had been that applications had been received for only 6,000 of the shares. They had, however, strong assumption for believing that 25,000 of the shares had been sold, but 19,000 had been sold by parties who did not hold them, and with whom the French Company were not treating. Efforts were being made to ascertain the exact number that had been sold. If the steps they were taking were successful, those who held these 19,000 shares would be in a position to run them up to what they liked. They held a meeting last evening, and he only arrived in London that morning with two of his colleagues, who were then present. M. Philippart could not possibly come, but until six o'clock the previous night he was to have come to attend the meeting. They were, however, on the eve of a battle, and certainly if it were necessary for any one to remain in Paris the right man to be there was M. Philippart, as no one was so able to look after their interests. Opposition had been raised against M. Philippart, but as that gentleman had stated he had the largest interest in the Company, and he knew all about the work they were engaged in. As far as he could he should be happy to answer any questions, but before concluding he would suggest that the meeting should now be further adjourned to the 20th February next. [A voice: Nonsense.] The matter was entirely in the hands of the shareholders. He was only suggesting what was thought best from being behind the scenes. If the meeting were further adjourned to that date he had mentioned he would himself undertake that one or two circulars should in the interval be forwarded to the shareholders, telling them how matters were going on.

Mr. HARCOURT TURNER stated that that was the third meeting which had been called at which adjournments had been asked for. That being so, and as the chairman had said he had good grounds for believing they would succeed, he should like to know what the good grounds were. As to M. Philippart being the largest shareholder, his calls had not been paid, and his shares were liable to be forfeited. He (the speaker) called a meeting last July as to the expediency of investigating the affairs of the Company, and a committee was then appointed, and he thought the time had now arrived when that committee should be put into action.

Mr. HENRY STAPLES asked several questions as to the actual result of the sale of the shares in the French Metropolitan Company.

Other shareholders made further inquiries relative to this sale, and also as to the general position of the Company, and one gentleman asked whether it was a fact that the parties referred to by the chairman as engaged in the sale of the shares had refused to hand over the proceeds of the subscription.

The CHAIRMAN, in reply, stated that it was a fact. This had been owing o the suggestion that, according to French law, the sale of the shares was illegal. The sale was made by a group to whom the French Electrical Power Storage Company had entrusted them for sale, who had then issued them. The issue was no doubt legal, and arrangements had now been made for paying over the money, providing that a circular were sent to those who had taken up the 6,000 shares, offering them the chance of withdrawing. This circular had been sent round, and up to the third day afterwards the buyers of only thirty shares had withdrawn. He did not say that others had not since withdrawn. As to Mr. Turner's question, there were reasons which rendered it advisable that they should not go too much into detail at a public meeting. The amount agreed to be paid to the French financial group for disposing of the whole of the issue of the shares in the French Metropolitan Company was £25,000, but if the whole were not sold they would get a commission on the number disposed of. He was not thoroughly acquainted with the arrangement, but he believed that that was it. The French Electrical Company (in which the Faure Company was interested) had to pay, by the terms of the original contract, by the end of this month £30,000 to the English Company, or the contract might fall to the ground. The French Company were not at the present time in a position to pay that sum, and, if necessary, an extension of time would be asked from the English Company. The English Company were in accord with the French Company, and knew everything that was being done in connection with the issue of the shares of the French Metropolitan Company, and there was every reason to believe that an extension of time would be granted by the English Company for the payment of the sum mentioned. The directors had nothing to hide, and they would be very glad to recognise unofficially the committee formed at Mr. Turner's meeting.

Eventually the meeting was adjourned to the 20th of February next, and the proceedings then terminated.

## BRAZILIAN SUBMARINE TELEGRAPH COMPANY (Limited).

Notice is given that the CABLE between St. Vincent and Pernambuco is REPAIRED, thereby restoring direct telegraphic communication with South America.

RICHARD COLLETT, Secretary.

8, Great Winchester-street, London,
4th December, 1883.

NOTICE of REMOVAL.—Messieurs HASELTINE, LAKE, and CO., Patent Agents, beg to announce that they have REMOVED to No. 45, SOUTHAMPTON BUILDINGS, CHANCERY LANE, opposite to their former premises.

TO ELECTRICAL ENGINEERS.—WANTED, SITUATION as ASSISTANT. Advertiser possesses good knowledge (practical and theoretical) of electrical work, and is good draughtsman and shorthand writer.—E., 6, Soames-street, Peckham.

ELECTRICAL ENGINEER WANTED.—WANTED, a thoroughly experienced PERSON to UNDERTAKE the immediate SUPERINTENDENCE of a TELEPHONE EXCHANGE. He will be required to take the supervision of the working of the Exchange, and also the erection of new lines and instruments. He must be a skilled electrician.

Reply, stating age, experience, qualifications, and salary expected, to H. B., office of this paper.

WANTED, FOUR SECOND-HAND WESTON ARC LAMPS,
to burn for five hours each. Must be in good condition. State price and particulars to

Messrs. J. and E. HALL, 23, St. Swithin's-lane, E.C.

Digitized by Google

## NOTES.

UNITED TELEPHONE COMPANY.—This company have declared an interim dividend at the rate of 5 per cent. per annum.

TELEGRAPHIC EXTENSION IN AMERICA.—The Postal Telegraph Company's line is being rapidly built between Chicago and St. Louis.

ANGLO-AMERICAN BRUSH CORPORATION.—Mr. Edward Woods, Vice-President of the Institute of Civil Engineers, has joined the board of this corporation.

ELECTRIC LIGHTING IN WORKSHOPS.—The Pullman Palace Car Works in the United States are to be completely fitted up with Brush electric lights and Swan incandescent lamps.

SOCIETY OF ARTS.—The Council of the Society of Arts have elected Sir Frederick Abel, C.B., D.C.L., F.R.S., as their chairman, in succession to the late Sir William Siemens.

EARTHQUAKE.—It is reported from Vienna that a violent shock of earthquake, accompanied by a rumbling noise, was felt at Agram at 3:15 a.m. on Wednesday. The movement was from west to east.

TO BE WOUND UP.—The North Woolwich Telegraph Works Company have determined to wind up. Mr. G. Fraser, of 2, Tokenhouse-buildings, E.C., the secretary of the company, has been appointed liquidator.

THE TELEPHONE IN ITALY.—It is stated that the Société Générale Italiennè des Téléphones have granted a concession for the working of exchanges in central Italy, and that work will be begun at once in Florence, Bologna, Pisa, and Livorgno.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the three days ended December 7th amounted to £1,615. The Brazilian Submarine Company's cable being now repaired, the publication of traffic receipts will be resumed.

THE INDIAN TELEGRAPH DEPARTMENT.—The new arrangement for concerted working between the Indian Postal and Telegraph Departments will result, according to the Indian papers, in the addition of from eighty to one hundred new telegraph offices by the close of the official year.

CITY AND GUILDS OF LONDON INSTITUTE.—On Monday last Professor Huxley presented the prizes to the successful students at the recent examinations held under the auspices of the City and Guilds Institute. The presentation took place at the Finsbury Technical College.

PHILADELPHIA ELECTRICAL EXHIBITION.—A circular has just been issued from the United States Treasury Department to the collectors of customs directing that the invoices of all imports intended for the Electrical Exhibition at Philadelphia shall contain a description of the apparatus, its value, and the marks and numbers upon it.

WORKS FOR SALE.—We notice that Messrs. Lyon and Turnbull, of Edinburgh, are to sell the works and plant of the Electric Carbon Storage and Apparatus Manufacturing Company of Scotland on the 20th inst. at the works in Coburg-street, Leith. The sale is made under the order of the High Court of Justice, the company being in liquidation.

THE FERRANTI DYNAMO.—During the progress of the Fisheries Exhibition, the Government officials watched very carefully the various systems of electric lighting, and as a result we understand that they have given the preference to the Ferranti system, and purchased a dynamo exhibited there, for the purpose of lighting a portion of the South Kensington Museum.

THE TELEPHONE IN EGYPT.—A telegram from Alexandria to a daily contemporary says:—"The Telephone Company in Egypt is doing good work. All the Government offices and ministries are in communication, and shortly lines will be established between Cairo and Alexandria, a distance of 150 miles." This company, it will be remembered, is one of the offspring of the Oriental Telephone Company of London.

THE CALCUTTA EXHIBITION.—A Reuter's telegram from Calcutta, dated Dec. 7, says:—"It has been ascertained from further investigation that the sudden extinguishing of the electric light in the museum on the occasion of the opening of the exhibition [as mentioned in a note in our last issue], was not due to any malicious act, as was at first supposed, but was caused by the electric current fusing the wires."

DEATH OF M. JAMETEL.—The death is announced of M. A. Jametel, chairman of the administrative council of the Société Générale des Téléphones from the formation of that company in Paris. He was an officer of the Legion of Honour. His funeral was attended by M. Cochery, Minister of Posts and Telegraphs, and many of the officials of the above company, one of whom testified to the excellent qualities of the deceased gentleman in a speech at the grave-side.

ELECTRIC LIGHTING OF SHIPS.—In a recent note we announced that the "Richelieu," a French war vessel, was to be lighted by the incandescent system. We take the following particulars of this installation from a French paper:—The lamps used are 210 Edison. The current is supplied by a Gramme dynamo driven direct by a motor designed by Mégy, of Paris, and made by Messrs. Soutter, Lemonnier, and Co. The machine and motor occupy a space of four square metres, and are about one metre and a half high.

THE MANSION HOUSE.—The General Purposes Committee of the Corporation of London will meet at the Guildhall on the 23rd January next to receive tenders for lighting the interior of the Mansion House by incandescent lamps. Plans and sections of the rooms, and other information may be obtained on application at the architect's office, Guildhall. Each proposal must be delivered by hand, at the hall keeper's office, Guildhall, between 12 and 1, and persons tendering are to attend the committee at 1 o'clock on the above-mentioned date.

THE LATE SIR WILLIAM SIEMENS.—Messrs. Adams and Scanlan, of 32, High-street, Southampton, have sent us some copies of photographs of the late Sir William Siemens, taken on the occasion of the visit of the British Association to that town last year, when Sir William occupied the presidential chair. The photos are most accurate as likenesses, and good specimens of photography as well. The copies sent us allow of a choice between profile, three-quarter face, and full face. Of the three we think we prefer the side face, though the others are capital photographs.

ELECTRIC LIGHTING IN THE CITY.—The Streets Committee of the Commissioners of Sewers will meet in the Guildhall on the 25th of January to receive tenders for lighting by means of the electric light certain streets of the city for a period not exceeding five years, and the parties contracting for lighting the public streets will have the privilege of laying wires to the houses along the route. The tenders are to be in accordance with conditions to be seen at the Sewers Office, and must be sealed, endorsed "Tender for Electric Lighting," and be delivered or addressed to Mr. Henry Blake, principal clerk, before two o'clock on the above date.

A SERMON HEARD A HUNDRED MILES OFF.—The Columbus,

Digitized by Google

Ga., and Montgomery, Ga., papers report that the opening hymn, prayer, and a portion of the sermon in the Sunday morning service at the Presbyterian Church, Columbus, Ga., were heard distinctly by telephone at Montgomery, Ga., over the telegraph wires recently. The cities are 100 miles apart. Mr. T. L. Ingram, the manager at Columbus, connected also with Macon on the same day, and equally good results were obtained in conversation between these two points, which are also about 100 miles distant from each other. It is now proposed to connect Augusta, Columbus, and Macon in one circuit, by way of experiment.—*Electrical World.*

The Spottiswoode Memorial.—The Royal Society have approved of the suggestion of Mr. Hodson, secretary to the Printers' Corporation, that the Spottiswoode memorial should be of the nature of a contribution to the Printers' Pension Fund, with which Mr. Spottiswoode had been connected as a man of business, and to which he was a generous contributor. The resolution containing this approval was moved by Mr. John Evans, treasurer of the Royal Society, at a meeting held last week, and ran as follows:—"That this meeting cordially approves of the suggestion to raise a memorial to the late William Spottiswoode, without prejudice to any special memorial to be raised by the Fellows of the Royal Society, and adopts the form of memorial recommended."

Electric Lighting in a Shipyard.—An installation of electric lighting has just been started at the shipyard of Messrs. Swan and Hunter, Wallsend-on-Tyne. It consists of a C. Crompton-Bürgin dynamo machine and six arc lamps of 2,000 candle-power each. The lamps are of the double differential type, with two sets of carbons, each set of which will burn eight hours. When one set is burnt out the other automatically switches itself in. They are very steady, and give a light of a pure white colour. The machine is driven by a six horse-power semi-portable engine, made by Messrs. Marshall, Sons, and Co., of Gainsborough, which is fitted with Hartnell's patent automatic expansion gear. The work has been carried out by Mr. Wilson Hartnell, of Benson's-buildings, Leeds, to whom much credit is due.

Overhead Wires in London.—The Parliamentary Committee of the Shoreditch Vestry have issued a report on the subject of overhead wires. They agree with the Newington Vestry that overhead wires ought not to be allowed, and that all telegraphic and telephonic wires should be underground. They had been informed by the vestry clerk that the vestry had no power to remove overhead wires unless they could be proved to be common law nuisances. The committee recommend the vestry to decline to join with St. Marylebone Vestry in the expense that might be incurred in taking legal action in the matter; and suggest that the Government should be communicated with and requested to determine the question of responsibility by legislative enactment. This recommendation has been agreed to by the vestry.

The Late Gale.—The storm which broke over the British Islands on Tuesday night and continued far into Wednesday morning proved very destructive to property and made considerable havoc amongst the telegraph wires. On Wednesday night the Post Office authorities gave notice of considerable delay in telegraphic communication with Nottingham, Sheffield, Liverpool, Manchester, Leeds, and all English offices north of the three last-mentioned places. Messages for Scotland and the north of Ireland could only be accepted at the sender's risk. The danger of having telegraph poles near enough to the metals of a railroad for the poles to be blown across them was illustrated near Durham. In Redhill cutting the East Coast express ran over two poles which had been blown down, but fortunately did not leave the rails. Altogether the Post Office linemen will have plenty of work to do all over the country.

Electric Light in Theatres.—The Edison installation at Niblo's Garden consists of one K dynamo, 55 volts electromotive force, capable of supplying current for 500 eight candle-power B lamps. At each performance of *Excelsior*, the Edison lights are in use as follows:—1st act, last scene, the electric torch held by the character "Light;" 2nd act, last scene, the Brooklyn Bridge; 3rd act, 1st scene, the discovery of the electric spark in Volta's laboratory. In the last scene, says an American contemporary, the ballet dancers are provided with wands, each having an Edison lamp on the end, and festoons of lamps are lowered from the flies above. At a given signal the entire number of lamps—400—are lighted instantaneously, producing a magical effect of great brilliancy. To instantly light such an immense number of lamps at their proper candle-power, is a very severe test on the regulating capacity of the engine and the dynamo.

New Cable in the Red Sea.—The news of the recent disaster at Souakim, and the defeat of the Egyptian troops by the rebels there, has caused the Egyptian Government to think seriously about laying a cable, or having a cable laid, to that place. According to a message despatched by the *Daily News* correspondent to that paper on Tuesday last from Alexandria, the Egyptian Government were on the point of making a convention with the Eastern Telegraph Company to tap their Red Sea cable and lay a branch to Souakim. The message further stated that the Eastern Company required no money from the Eygptian Government, and engaged to lay the line and keep it in working order in return for certain guaranteed privileges. It was expected that the convention would be signed on Wednesday. The telegraph staff had already left for Suez before the message was sent. The negotiations were, however, still proceeding when we went to press.

Accident from Lightning.—According to a communication made to the Paris Academy of Sciences by M. Laugier, two persons were killed by lightning on the Rambouillet territory. The accident occurred on the 10th of last month, at 11:30 a.m. The storm began by a violent hailstorm, followed almost immediately by a flash of lightning and a clap of thunder, the latter so closely following the former as to appear simultaneous. A second flash followed about five minutes afterwards. The first flash killed two agriculturists, a husband and wife, who, to avoid the hail, had taken shelter under a poplar tree in the middle of a field, about 500 metres distant from the houses of the hamlet of Grenonvilliers. The tree was cut in two; the two victims, whose clothes were torn and scorched, were struck on the head, their skulls being fractured and pierced with a large deep hole, of the same character as would be produced by a projectile of large calibre. A third person, a woman, who was under the same tree, merely had her clothes torn to shreds and a slight burn on the head and one of the cheeks.

Domestic Lighting.—For the last three months, Mr. C. H. Gimingham, F.C.S., manager of the Edison and Swan United Electric Light Works at Benwell, Newcastle-on-Tyne, has lighted his house by electric lamps. Mr. Gimingham has dispensed entirely with the use of gas, and depends upon forty low tension incandescent lamps of various candle-powers, according to their position. The lamps are arranged independently of each other, with the exception of the electroliers, in which the lights are turned on and off in groups. The current is supplied by a small Siemens machine, driven

Digitized by Google

by a ½ horse-power Otto gas engine. Connected with the machine is a set of secondary batteries, which, while the engine is in motion, stores the excess of current for use when the engine has been stopped. No holders are used for the lamps, which are suspended from platinum wire hooks attached to flexible wire cords, and have small opal glass bell-shaped shades. A novelty in the shape of an electrolier formed to represent a large basket of real ferns pendent from the centre of the ceiling is to be seen, the lamps being placed amongst the foliage.

Catalogues.—Messrs. H. and E. J. Dale, of 4, Little Britain, E.C., have just issued a second edition of their catalogue of electrical and scientific apparatus. It is copiously illustrated and neatly printed. For those who want apparatus for experiments at home or lecture purposes such a catalogue as this is extremely useful. The student who is just beginning to wade through a text book of electricity will be able to familiarise himself with the outward appearance of many instruments described therein, but which he will not find illustrated. He will probably at the same time find his fingers itching to possess the different batteries, magnets, induction coils, and what not. Taken as a whole, Messrs. Dale's catalogue is a very useful publication of its class. By the way, we notice that galvanometers and galvanoscopes are persistently spelt galvonometers and galvonoscopes on pp. 16 and 17.—We have another, but more modest little price list on our table, published by the Electric Appliance Company, of 4, Trafalgar-buildings, Charing-cross, W.C. It contains a useful description of how to fit up electric bells, with illustrations, and the prices of Leclanché batteries, bells, &c.

The Telephone in Aberdeen.—Some quick work in the way of putting up telephone wires was done the other day in Aberdeen by the staff of the National Telephone Company. The warehouse of Messrs. W. Paterson and Sons, wholesale druggists, 133, Gallowgate, who have just become subscribers to the Aberdeen Exchange, is exactly 830 yards from the company's Market-street centre. The erection of the wire was commenced on Saturday last, and finished at 11:30 a.m. on Monday. The line was then in working order, and Messrs. Paterson in full communication with the other members of the exchange, the work of connection having only taken six actual working hours. The connection of Messrs. John Bisset and Co., 37, Queen-street, which required 424 yards of wire, was also begun on Saturday, and was completed at 4 p.m. on Monday, having occupied five and a half working hours. The connection of Mr. James Butchart, Belmont-street, a few weeks ago, was even more quickly carried out. His order was received at 3:30 p.m., and although the men had to be recalled from the west-end of the town, the connection was complete, and Mr. Butchart speaking to his friends by its means a few minutes after six o'clock on the same evening, the whole work having taken only two hours. The wire in this case was 480 yards long.

A Standard Battery.—M. Emile Reynier has constructed a standard cell. It consists of a zinc-copper couple, rendered very constant by the increased size given to the copper plate. This plate has a surface of 30 decimeters, or three hundred times that of the zinc plate. This latter is composed of a zinc wire of 3mm. diameter, fixed in the centre of the cell. It can be made to dip more or less into the electrolyte at will. The copper plate is outside the zinc, in the form of a corrugated cylinder, the corrugations being very deep. The cell has a resistance of 2 ohms to 4 ohms, according to the liquid used. Its E.M.F. only loses $\frac{1}{100}$th part of its value after being two hours at work, and giving one milliampere current. With ordinary zinc in dilute sulphuric acid, the cell gave ·94 volt; with amalgamated zinc and the same liquid, it gave 1·07 volt. In a solution of salt water, ordinary zinc gave ·78 volt, and amalgamated zinc ·82 volt. In a solution of chloride of zinc the former gave ·85 volt, and the latter ·86 volt. In a solution of sulphate of zinc the former gave 1·00 volt, and the latter 1·04 volt, whilst in a solution of caustic soda the E.M.F's given were respectively 1·06 volt and 1·09 volt. The liquid preferred by M. Reynier is a salt water solution, composed of 250 parts of salt to 1,000 parts water, the latter to be filtered.

Researches on the Glow Discharge.—In a recent number of the *Ann. Phys. und Chem.*, Herr Herz described his researches on the glow discharge. We take the following abstract of his article from the *Journal of the Chemical Society*:—"The author has investigated several questions as regards the phenomenon of the glow discharge in rarefied gases; the source of electricity used was a battery of 1,000 secondary Planté's elements, arranged in series of fives. By the aid of this battery and various forms of apparatus, which are described at length in the original memoir, the author shows (i.) that the electric discharge in rarefied gases is not, as Gassiot supposed, necessarily a discontinuous phenomenon; but under certain conditions, *i.e.*, by the use of a battery of sufficiently low resistance, it has all the properties of continuity. (ii.) The luminous rays from the cathode are a concomitant phenomenon of the discharge, but this cause is not identical with that of the current; these rays have practically no electrostatic or electrodynamic properties. (iii.) The illumination of the gases by the glow discharge does not arise from a phosphoresence induced directly from the current, but only from the cathode rays. These rays are electrically indifferent; they resemble rays of light most nearly, and their inflection on the approach of a magnet may be considered to be analogous to the phenomenon of plane polarisation of light."

Edison System at the Louisville Exposition.—We take the following description of the lighting of this exposition from the New York Edison Company's latest *Bulletin*:—This is the first exposition building ever lighted throughout by incandescent lamps. The southern exposition building is one of the largest structures of its kind ever built, the area of the main building being 677,400 square feet, with an average interior height of 40ft. To illumine this vast space the Edison Company have installed 3,998 sixteen-candle Edison lamps, equal to 63,968 candles, an average of 175 square feet per lamp. The estimate given by gas officials for lighting the same area was one six-foot burner to each 45 square feet. Not only does the Edison estimate compare favourably in regard to figures, but, in the opinion of the public, the building is lighted far more satisfactorily than could be done by the same number of gas jets. Estimates were made by various gas experts to light the building with gas, but they called for from 7,000 to 12,000 gas jets to accomplish the results attained by the Edison Company with less than 4,000 lamps. The contract calls for the installation of 4,600 Edison lights of 16 candle-power each. To supply these lamps fifteen dynamo machines have been installed, together with the requisite engines to drive the same. The copper wire used for the conductors throughout the building weighs over 40,000 pounds, and would measure 40 miles in length, if stretched out in a straight line. This plant is the largest ever installed to light a single building, and is equivalent to a gas plant manufacturing 35,000 cubic feet per hour. The contract for this plant was signed by the Edison Company July 3rd, work was commenced July 9th, and on August 1st

Digitized by Google

all the conductors had been put in place and the current was passing, supplying light to the night circuit. Even as early as July 24th, the largest part of the plant had been installed. The total capacity of the plant is 6,000 lamps of 16 candle-power each, but there are in use only about 4,800, including those outside the building.

THE MID-LONDON ELECTRIC RAILWAY.—Signs of opposition to this proposed railway having manifested themselves, Mr. Arthur T. Atchison, one of the engineers of the scheme, writes to the *Standard*, offering a few explanations as to the nature of the intended operations. He says:—"It is perfectly true that the projectors of the scheme hope to acquire their route without paying anything for the ground they take—except, of course, at the sites of the proposed stations, where some house property has been scheduled. It is certainly not intended to follow in Oxford-street and Cheapside the example set by the state of Cannon-street for months past, as it is proposed to construct the whole line by tunneling from the station sites in both directions. There would thus be no obstruction to traffic or interference with the business of tradesmen on the route during the progress of the works. The stability of lofty buildings along the line will in no way be imperilled, as it is proposed to tunnel throughout in the blue clay with an advancing shield, which would always be followed up closely by the permanent lining of the tunnel, thus avoiding any chance of the smallest slip in the roof or sides. It is probably true that permanent ventilating shafts in crowded thoroughfares, if proposed, would alone be sufficient to prevent the scheme being carried out; but as there will be no foul gases evolved by the motors, they would be unnecessary; and further, as the up and down lines will be in distinct tunnels, the working of the traffic will cause sufficient circulation of air throughout."

SIR CHARLES DILKE ON SCIENCE.—The member for Chelsea was very hard down upon science upon the occasion of the distribution of prizes to the students at the Hammersmith (Broadway) Science and Art Classes on Tuesday night. Sir Charles stated that "in the whole South Kensington system the word science was put before the word art, and the majority of those who had just taken prizes belonged rather to the science than the art branch of the classes. He blushed to say that his sympathies were rather with the art than the science side. Science in these days seemed more able to take care of itself than art. Goethe expressed this by saying, 'Take care of the beautiful; the useful can take care of itself.' In these days when science ran riot about us, he was inclined to think that art needed more care and attention at the hands of the community generally than science. As a democratic politician he thought he could defend that point of view from a democratic standpoint. Science had been called democratic, but art was still more democratic. It had been contended that science in the long run rather tended to make the rich more rich, and sometimes in its indirect effects the poor poorer. Before moral and intellectual pleasures, however, all men—poor and rich—were potentially equal, and the poor man who had feeling was superior to the rich vulgarian who was unblessed by that sense. But although art was undoubtedly democratic, unfortunately it entered less into daily life than it had done in many cases in the past. The sensationalism, worry, and fuss which might be considered the chief characteristics of the age were fatal to art. Many might with sadness quote the phrase, 'What shall it profit a man if he gain the whole world but lose his own soul.' He would ask whether in inventing the telephone and other things in the present day we were not, to a certain extent, losing our soul. We were losing the love of the morally beautiful and the morally true, but he believed this was only a passing phase. Let art men refuse to be crushed by their scientific friends, and let them make that which, according to Darwinian principles, all ought to make, a fight for life."

THE RECENT CELESTIAL PHENOMENA.—The recent gorgeous sunsets have given rise to considerable correspondence in *The Times* and other papers. Mr. Norman Lockyer advanced the theory that the phenomena were connected with electricity, and Mr. W. H. Preece writes in support of his views in the following strain:—"I think I can add one link to Mr. Lockyer's chain of reasoning. If we assume that the mass of volcanic matter projected with such force into the atmosphere in the Straits of Sunda was highly electrified, then it must have been electrified with the same sign as that of the earth, viz., negative. Therefore, when the force of projection had exhausted itself, the cloud of matter would be subject to two other forces besides gravity—the repulsion of the electrified earth and the self propulsion of each particle of electrified dust. The first would determine the tenuity of the cloud, for the lighter the particles the further they would be repelled, and the heavier the particles the quicker they would descend. It is quite possible to conceive that they might be so minute and so highly electrified as to reach the utmost confines of our atmosphere, where they would remain as long as they remained electrified. The second repulsive force would cause the particles to spread out continuously in a horizontal plane until they would cover an area determined only by their quantity. When we take into consideration the movements of the atmosphere and the rotation of the earth, I see no reason to doubt that an immense cloud of highly electrified matter, projected into the atmosphere in Java, could spread itself in the higher regions of the atmosphere over an area equal to that of Europe. That this is not fanciful is proved by the behaviour of smoke. I have often watched when at sea on a still calm day the black smoke of some passing steamer rise to some determined height, and then gradually spread itself at an equal and constant distance from the sea like a great flat pall. I have also seen on land the smoke from some manufacturing shaft blown gently by the wind, follow the curves of the land, remaining always at the same distance from the ground, but gradually spreading outwards in every direction. I have also seen two lines of smoke refuse to coalesce, but repelling each other exactly as they ought if they were similarly electrified. That smoke is, therefore, negatively electrified, I firmly believe, though I have never tested it. Now, that this wonderful atmospheric disturbance was accompanied by extraordinary electrical disturbance was shown, not only by Captain Watson's observations near the spot, but by Professor Smith's records at Madras, and hence it requires no great stretch of the imagination to conceive electricity playing a great part in the recent gorgeous display of atmospheric effects."

A NEW ARC LAMP.—On Tuesday last Messrs. Clark and Co., exhibited a new arc lamp, the joint invention of Messrs. Clark, Clark, and Bowman, at 411, Brixton-road, S.W. The chief characteristic of the new lamp is a very delicate feeding arrangement which conduces greatly to the steadiness of the light. The parts which govern the feed are all in a shunt circuit, and consist of two electro-magnets and a small and very sensitive swinging armature, which when the arc becomes too long and the resistance too great is attracted by the magnets. The attraction of this armature puts two more electro-magnets in circuit, and they in their turn attract another armature attached to the end of a gripping lever. The other end of this lever grips the carbon and

Digitized by Google

prevents its downward movement, so long as the armature end remains unattracted, but the moment it is pulled down the grip is released and the carbon feeds. The distance through which both armatures must move when attracted can be regulated at will by two small stop-screws, so that the length of the arc can be increased or decreased whilst the lamp is burning with ease. This was clearly shown by the inventors on Tuesday night. The bottom carbon holder is fitted with an armature, which armature is attracted by an electro-magnet in the main circuit. To keep the carbons in contact before the lamp is lighted, a spring is provided which tends to push the lower carbon upwards. When the current is first turned on it energises the above mentioned electro-magnet; this attracts the armature attached to the bottom carbon holder, the carbons are separated, and the arc struck. This is all that is required of the main circuit. Directly the arc becomes too long, the electro-magnets in the shunt circuit become energised, and the upper carbon is fed as before described. The current was being supplied on the occasion of our visit by a 40-light Brush dynamo, driven by one of Marshall's fixed engines of 20 h-p. nominal, but which would be giving something like 30 to 35 actual h.-p. The number of lamps on the circuit was about 40, and they were all connected up in parallel. There were also a few incandescent lamps in circuit to illustrate the readiness with such lamps could be run in combination with the arc lamps. Each of the new lamps requires an E.M.F. of about 40 volts and a current of eight amperes, whilst they absorb about $\frac{3}{4}$ h.-p.—at least, so we were told. The lamps are used to light the outside and interior of several shops in the Brixton-road, one large grocer's shop being entirely lighted by this means. We were informed that a regular weekly rent is paid for the light, and that it is much appreciated by those who use it. The large grocer just mentioned, in addition to lighting his shop, makes use of a Gramme machine (converted into a motor) to grind his coffee. The Clark-Bowman lamp has single carbons, the inventors using Siemens's cored make, a hard core for the positive and a soft core for the negative carbon. They state that they have tried many makes, but none which have proved so satisfactory as these. The light given by the lamps is excellently steady, and there is none of the jumping, flickering, and winking to which some arc lamps seem so liable.

A Tricksy Motor.—The *New York Times* gives a capital account of a trial of Mr. Leo Daft's motor, which took place on Nov. 24, on the Saratoga, Mount M'Gregor, and Lake George Railroad. The correspondent of the above paper, who was present at the trial, says:—"Mr. Daft had prepared a stretch of track a mile and an eighth in length and covering a steep grade and a sharp curve upon which to run his motor, which, weighing two tons, had more the appearance of a tender to a pony locomotive engine than anything else, and was about 8ft. long, 4ft. wide, and 5ft. high. Its working machinery—the armature, the receiving dynamo, the contact wheel, and connecting wheels—was concealed from inquisitive eyes. The Mount M'Gregor Railroad is narrow gauge. The passenger cars weigh about five tons each. It was to one of these coaches that the motor was tied—there being no coupling-pin at hand—with a piece of 3in. rope. Along the centre of the track a third rail was laid, and from this rail the electric power was taken up by the motor. The electric current in this instance was generated by dynamos at a factory one-eighth of a mile from the railway station and 500ft. from the track, to which it was led through wires. The generating engine was 25 h.-p. The current is fed to the central track, and is taken therefrom by a contact wheel, which in turn transmits it to a receiving dynamo and causes the revolution. This is carried to the axles by two pulleys, differing in size and connected by a steel belt. A switch placed on the upper section or platform of the motor, in front of the driver or engineer, regulates the speed and governs the forward or backward motion. Another switch controls the brake, a double magnet, by means of which the motor may be stopped, the inventor claims, with more than the suddenness of the air-brake." The correspondent then gives an account of the outward journey, which was made up a steep gradient and accomplished in safety, the $1\frac{1}{8}$ mile being covered in 11min. The return trip was not destined to be such plain sailing. The correspondent says:—"The return trip was the feature of the occasion. As has been remarked, the grade was 70ft. to the mile, and the motor and car—the latter taking the lead—began to traverse the distance with accelerating speed. The passengers were intently watching the motor, when, as the curve was reached—a curve with a radius of 1ft. in 20ft.—there was a sudden snapping of the bell-cord that passed from the motor to the car. An instant later the motor, running 10 miles an hour, had jumped the track, and the gentlemen riding thereon were hurled through the air by the sudden stoppage, and many of them half buried in the soft sand on either side the road-bed. Mr. E. N. Dickerson, jun., and Mr. J. M. Mitchell, both young attorneys, of New York, fell directly in front of the motor as it and the car parted company, but, fortunately, the motor's progress was suddenly checked by the wheels ploughing into the sand, else these gentlemen must have been seriously injured, if not instantly killed. The car had meantime been stopped by applying the brakes. The motor was a complete wreck, its electrical gearing being scattered in every direction, or bent into unrecognisable shapes beneath the framework. It showed that electric motors and steam locomotives somewhat resemble each other, after an accident, at least, if not before. The forward end of the motor was thrown about two feet beyond the outer rail of the curve, while the hind wheels were resting on the ties close to the inner rail. A brass bell weighing about 30lb. was broken from its hangings and fell near Mr. Dickerson's head, while another gentleman found himself covered with fragments of the pulleys—thin iron wheels which carried the power from the dynamo to the axle. Others were covered with sand or choice Saratoga mud, while silk hats became part and parcel of the general ruin that had been so lavishly dispensed by the hand of chance. There had been a great and sudden collapse of everything, from enthusiasm to electric energy. The life was gone from everything. There was at first a general feeling that a darker shadow than the destruction of the inventor's machine had fallen upon the event. But when the unfortunate ones began scrambling to their feet, brushing the dirt from their clothes, wiping their faces, pushing the dents out of their hats, working their knee-joints and straightening their umbrellas, there was a great feeling of relief that things were no worse in a physical point. Mr. Daft, from his gentle manipulation of the little switch on the motor and his happy, satisfied seat of success, where he sat serene a moment before, was lifted out of a very soft spot between the two tracks, looking very pale and more serious than ever. As his friends gathered about him he pulled himself together slowly, looked ruefully at the ruin at his feet, stepped upon the fragments of a wheel, and said: 'We were going too fast.' Those who stood near did not ask him to make affidavit to this statement. The evidence was before them."

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 79.)

**Theories of Electro-Chemical Action.**—Various theories have from time to time been proposed to account for the leading phenomena of electrolysis, but none of them have as yet been very clear or satisfactory. One of the best is that propounded by Faraday. He considers that electrolysis resulted from a peculiar corpuscular action developed in the direction of the current; and that it proceeded from a force which was either added to the affinity of the bodies present, or determined the direction of that force. That the electrolyte was a mass of acting particles, of which all that were in the course of the current contributed to the terminal action, and in consequence of the affinity between the elements being weakened, or partially neutralised by the current parallel to its own course in one direction, and strengthened and assisted in the other, the combined particles acquired a tendency to move in different directions. The particles of one element, *a*, cannot travel from one pole to the other, unless they meet with particles of an opposed substance, *b*, ready to move in the opposite direction. For in consequence of their increased affinity for these particles, and the diminution of their affinity for those which they have left behind, they are continually driven forward.

Any tolerably complete theory of electrolysis of a fundamental character must, however, be a mechanical one, based upon the assumption of molecular motion, and expressible in mathematical and geometrical terms. Whilst also the theory must represent the kind of molecular motion which constitutes an electric current, it must also be consistent with the numerous and varied phenomena attending electro-chemical action. And as the essential kinds of molecular change which occur at the electrodes are probably more or less modified in every different case, a complete theory must admit of varied application. Clausius considers that the atoms or groups of atoms forming a molecule of an electrolyte revolve around one another, similarly to planets, and are sometimes nearer to and sometimes farther from each other. ("Poggendorff's Annalen," CLVI., pp. 618 to 626.) Favre states (*Comptes Rendus*, Vol. LXXIII., p. 971) that in each voltaic couple the molecules are electrolysed *successively*, and that when the *absolute number* of vibrations which correspond to a given intensity of the current have been determined the *absolute weight* of the chemical molecules will be known (*Journal Chemical Society*, 2nd series, Vol. X., p. 25).

The immediate or primary electrolytic changes are evidently a result of molecular energy transmitted along the wires from the source of the current; and the energy so transmitted is substantially the same in its chief properties and electrolytic effects, whether it proceeds from a voltaic battery, a thermopile, or a dynamo electric machine. Any theory, therefore, which explains electrolysis must also be consistent with the fact that in the act of electrolysis the homogeneous electric energy is converted into potential molecular energy as varied in kind as the properties of the liberated elements. It must also explain why the same element may in certain cases be an anion in one combination and a cation in another.

**Distinction between Voltaic and Electrolytic Action.**—These two actions are almost entirely the converse of each other; the former is a consumer, and the latter a producer of potential molecular energy. In voltaic action substances are burned, in electrolytic they are unburned. In a voltaic cell potential or stored-up energy of elementary substances is converted into electric current; in an electrolysis vessel current is converted into stored-up potential energy in the elementary substances liberated at the poles.

**Intimate Connection of Voltaic and Electrolytic Action.**—As in nearly every voltaic circuit the current produced at the positive surface decomposes the liquid at the negative one, and in nearly every electrolytic circuit voltaic currents are produced by difference of chemical composition of the liquids in contact with the two electrodes, nearly every voltaic circuit is partly electrolytic, and nearly every electrolytic circuit is partly voltaic.

According to these views, voltaic action is chemico-electric, and a case of chemical union in all cases; and true electrolytic action is always a case of electro-chemical separation, sometimes accompanied by chemical union at the electrodes.

The various phenomena of electrolysis are produced not only by electric currents proceeding from an external source, but also by those produced in the electrolyte itself; and also not only by currents generated and flowing in circuits of measurable magnitude in that liquid, but also by others in circuits so small that they cannot be measured.

In the case of an ordinary voltaic cell or electrolytic vessel, the positive and negative surfaces are sufficiently far asunder to enable us to perceive the action at each; but in those of "local action" and minute circuits, such as those in cases of deposition by "simple immersion," or the chemical substitution of one metal for another, as when iron becomes coated with copper by simply immersing it in a solution of cupric sulphate, the positive and negative surfaces of each circuit are so excessively small, so exceedingly near together, and the circuits are so numerous, that they cannot be separately observed, and the entire immersed surface of the metal is covered with inseparable voltaic and electrolytic actions.

The substances set free by electrolysis do not always appear; the instant they are liberated they are subject to ordinary chemical action by contact with the liquid, the electrodes, and the atmosphere. Thus, when potassium is set free at the cathode from a solution of any of its salts, it is instantly oxidised into potash; or oxygen set free at a copper anode instantly oxidises the copper. Other relations of electrolytic to ordinary chemical action have already been described.

These facts show the intimate connection of chemical, electro-chemical, and voltaic phenomena; that the study of electro-chemistry requires considerable knowledge of voltaic electricity; and that the modes of electrolysis require to be classified according to the magnitude of the electric circuits and the degree of complexity of the voltaic and electrolytic combinations employed. Neither voltaic action nor electrolysis can be successfully studied without also a previous knowledge of general chemistry. As the subject of these articles is electrolysis and not voltaic action, the latter will only be explained so far as is necessary to elucidate the former.

**Modes of Generation of Voltaic Currents.**—A voltaic current may arise—First, from the contact of two metals with one liquid, *e.g.*, zinc and copper in dilute sulphuric acid; second, from the contact of one metal with two liquids, *e.g.*, two pieces of silver, one in a solution of potassic cyanide, and the other in argento cyanide of potassium, the two liquids touching each other through an intervening porous partition, or by lying upon each other; or third, from the contact of two metals with two liquids so arranged, *e.g.*, zinc in dilute sulphuric acid, and copper in a solution of cupric sulphate.

The strength of current thus obtained is usually the greater the more wide the difference in the chemical properties of the metals and liquids employed, and is commonly the greatest with the combinations of two metals with two liquids.

**Source of the Current.—Theory of Voltaic Action.**—Two rival theories of the source of the current have long been entertained—First, that of Volta, that the current is due to contact of dissimilar conductors of electricity; and second, that of Faraday and other English investigators, that it is due to chemical action. Neither of these views, however, is completely satisfactory, or has been universally accepted.

If, however, we adopt a theory that *the molecules of substances* (those of chemically active bodies in particular), *are in a state of ceaseless motion* (that of frictionless bodies in a frictionless medium, the universal ether) *until they chemically unite*, an efficient cause of the current (and of chemical action) becomes at once exceedingly clear.

Digitized by Google

According to this view, which I may term the Ceaseless Molecular Motion Theory of voltaic and chemical action, neither contact nor chemical action is the real dynamic cause of the current, but the true cause is the potential molecular energy of the corroded metal, and of the corroding element of the liquid with which it subsequently unites, and chemical corrosion is only the *process* or *mode* by which the molecular motions of those substances are transformed into heat and current.

Both the heat and electric current produced during the chemical corrosion of metals by electrolytes are recognised modes of motion, or forms of active molecular energy, and as motion or energy cannot be created, but can only result from the expenditure of some other form of motion, these movements are derived from the original metal and liquid, and the corroded metal and liquid employed have, after the action, lost to a greater or less extent their power of further producing heat or current.

According to this view, also, contact is only *a static condition* which enables the molecular motions of the one substance to modify those of the other, and thus produce static electric polarity; and this, if sufficently strong, produces corrosion and the new modes of motion, namely, heat and current.

**Electrical Theory of Chemistry.**—This theory (attributed to Berzelius) assumes that the chemical union of any two substances is an electrical act; *i.e.*, that during contact, previous to union, the one substance is relatively positive, and the other relatively negative, and that the act of union is a consequence of these states; also that during the act of union the two electric states neutralise each other and produce heat and current.

In accordance with this theory, and with the voltaic series of metals, the various elementary substances have been arranged in the following order, the most strongly electro-positive substance being placed first, and the most negative one last:—Caesium, rubidium, potassium, sodium, lithium, barium, strontium, calcium, magnesium, aluminium, zinc, cadmium, iron, cobalt, nickel, lead, tin, copper, mercury, silver, palladium, gold, iridium, rhodium, platinum, hydrogen, osmium, antimony, tellurium, arsenic, silicon, carbon, phosphorus, selenium, iodine, bromine, chlorine, nitrogen, sulphur, fluorine, oxygen.

The electrical theory of chemical action may be reasonably extended from that of metals and electrolytes to that of all non-conducting elements in non-conducting liquids, because resistance to conduction is only of degree, and not infinite. If therefore, the electric polarity produced by the molecular motions of bodies is sufficiently strong, and the electrical circuits sufficiently small, chemical union and electrolysis in non-conductors must occur.

The deposition of copper and silver from aqueous solutions of their salts by immersing in them a piece of ordinary phosphorus, are good examples of electrolysis produced by a non-conducting element in conducting solutions, and the separation of hydrogen from pure water by contact of a zinc-platinum couple is an instance of electrolysis by conducting bodies in a non-conducting liquid. And the chemical decomposition of non-conducting liquids by non-conducting elements may be regarded as only an extension of the same kind of action.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for November, 1883, amounted to £21,480. For the period from 1st January to 30th November, 1883, they were £236,800, against £223,863 for the corresponding months of 1882, and £218,291 for the same period of 1881.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The directors of this company have declared an interim dividend of 3s. per share, or 6 per cent. per annum, free of income-tax, for the quarter ended Sept. 30 last.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 80.)

Another method for automatically adjusting the pressure between brake blocks and pulley is that due to M. Marcel Deprez, which is shown in Fig. 10. A is the brake pulley embraced by a pair of jaws, M M, which can be tightened by means of the lever L. To the end of this lever a weight, Q, is applied, and the pressure thus obtained depends partly on the weight and partly on the angle which L forms with the horizontal. Pulley B is loose on the shaft, but rigidly connected to one of the jaws, M, so that the jaws and the lever L can turn round the shaft, together with pulley B.

The friction tends to turn the whole system in the direction of the arrow, and the weight P, which is suspended on a cord from the circumference of the loose pulley, resists that tendency. Should the friction increase to such an extent as to lift this weight, then the jaws and lever L will rise until the decrease of pressure due to the steeper angle of the latter again allows the pulley to slip under the brake blocks. Care must be taken to make the lever of such length that the point of attachment of weight Q may come as nearly as possible into the centre of the shaft, so that it shall not produce any torsional effect. As the weight of the jaws can be

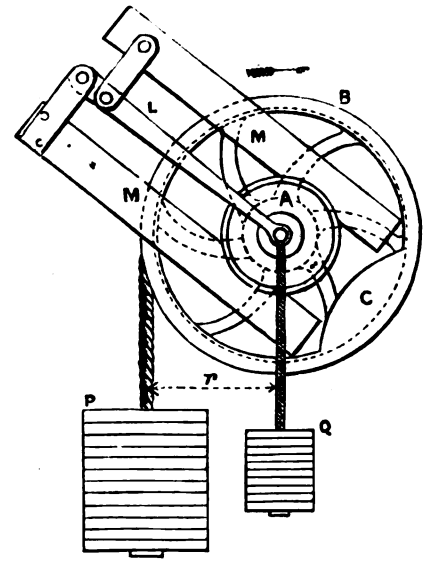

FIG. 10.—Deprez's Brake.

correctly balanced by a counter-weight, C, on the loose pulley, the only torsional momentum acting against the power in the shaft is $Pr$, and this multiplied by the angular velocity $2\pi n$ gives the mechanical work destroyed in friction per minute.

If P be given in pounds and $r$ in feet the horse-power is—

$$\text{H.-P.} = \frac{1}{33000} 2\pi r n \text{P}.$$

Probably the most ingenious compensating arrangement, and certainly the most successful one, is that introduced by Amos and Appold into the brakes belonging to the Royal Agricultural Society of England. The largest of these brakes is capable of absorbing 100 horse-power at 100 revolutions. It consists of three brake pulleys 5 feet diameter by 7 inches wide, mounted on the same shaft, and each having its own brake strap, weight, dashpot, and compensating lever. For large powers all three pulleys are used as brakes, and the motion is transmitted to the shaft by means of universal couplings with sliding sleeves, so that no end thrust may come on the shaft.

For small powers only one or two of the pulleys need be used, the brake strap being in that case removed from the third pulley which, if desired, can then be used to receive the power from the prime mover by means of a belt. In side elevation this brake resembles that shown on page 33. The brake band is tightened by a right and left-handed screw,

Digitized by Google

but in addition to this its grip over the pulley is varied automatically by a compensating lever or pendulum, the action of which will at once be understood by comparing Figures 11 and 12. The former shows the position of the lever immediately after an excess of friction has shifted the brake band somewhat in the direction of rotation; the latter shows the position of the lever which would result from a sudden decrease of friction or a sudden increase of the weight to which the brake is loaded. In the first case the lever slackens and in the second case it tightens the brake, thus automatically re-establishing equilibrium. Since the work done is proportional to the leverage of the load it is important to

Amos and Appold's Brake.

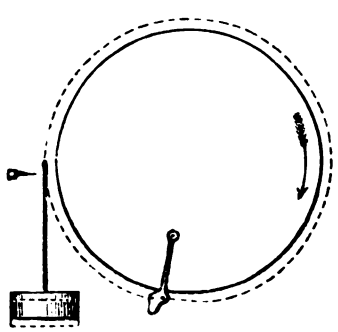

FIG. 11.

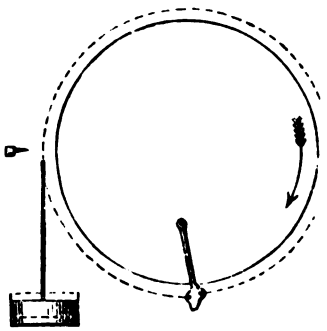

FIG. 12.

Fig. 11 is a diagram of Pendulum when Slackening the Brake Strap.
Fig. 12 is a diagram of Pendulum when Tightening the Brake Strap.

measure exactly the horizontal distance between the centre of shaft and the point of suspension of the load. This distance is variable by reason of the brake blocks wearing away, and to facilitate the measurement the pin to which the load is suspended is turned to a cone on both ends, the point of the cone being used to mark the distance on a steel gauge, the forked end of which is laid against the shaft. By taking this distance on either side of the pulley a very accurate average is obtained.

For a rough and ready test Mr. F. T. (now Sir Frederick) Bramwell recommended to the meeting of the Institution of

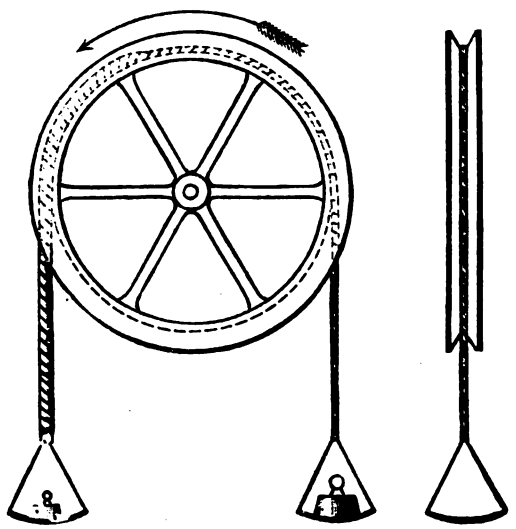

FIG. 13.—Ayrton and Perry's Brake.

Mechanical Engineers, in 1876, a simple form of brake consisting of a belt laid over the fly-wheel of the engine to be tested, one end being fastened to the ground by a spring balance, the other being weighted.

The difference between the dead weight on the one side and the pull on the spring balance on the other side is the load on the brake. This arrangement is also self-compensating, for, should the weight be raised by an excess of friction, then the tension of the spring, and with it the grip of the pulley on the belt, will be reduced until slipping again takes place.

A brake similar in principle but with a different compensating arrangement has lately been devised by Professors Ayrton and Perry. It is shown in Fig. 13, and consists of a grooved wheel, over which is laid a cord carrying weights on either side. The cord consists of two pieces of unequal thickness, the junction being somewhere in the groove. The thicker and rougher part carries a small weight on the descending side of the wheel, the thinner and smoother part carries a larger weight on the opposite side. An excess of friction will lift this weight, causing more of the smooth and less of the rough rope to be within the groove, thereby diminishing the total friction until the wheel again slips under the cord. An excess of weight on the ascending side will have the opposite effect, bringing more of the rougher cord into the groove until the increase of friction so caused suffices to balance the increased weight. According to the inventors the exact form of the junction between the two cords is of great importance. It should be more of a knot and less of a taper than in the figure in order that the dynamometer should compensate well.

The author has found the brake shown in Fig. 14 very useful in testing small electro-motors.

A O B is the beam of an ordinary balance suspended from a stand by means of a screwed spindle and thumbunt, which latter resting not immediately upon the stand, but upon an interposed spring, S, permits a variable and somewhat elastic tension in the cord D C E to be obtained. The two ends of the cord are fastened equidistantly from the centre gudgeon

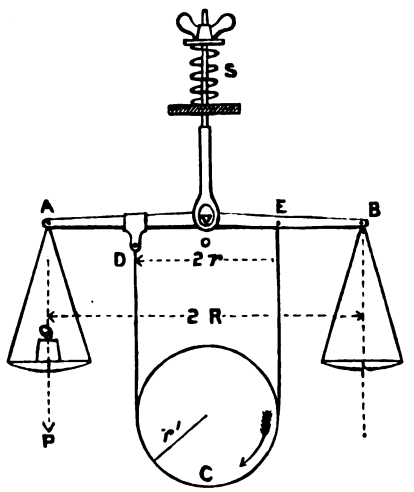

FIG. 14.—Kapp's Brake for Small Electromotors.

O, and approximately to the radius of the pulley C. This pulley is keyed on the shaft of the motor. To get the cords exactly equidistant from O it is best to suspend equal weights, and having fastened one end, to shift the other until the beam is horizontal. If the cord be attached as shown in the figure, namely one end to a clip, D, and the other direct to the beam, the two cords do not remain equidistant from O if the beam assumes an inclined position. If the end A be raised, the distance of D from the centre line increases, whilst that of E diminishes, and at the same time the whole of the cord is slightly slackened. The friction on the cord tends to draw B down, and must be balanced by placing weights in the scale A. An excess of weights and a consequent drop of A has the effect of slightly tightening the cord and reducing the leverage of D more rapidly than that of E. In consequence of this the motion of the beam to either side of the horizontal is kept within narrow limits. By varying the spring S any degree of delicacy can be obtained. Weights must be added or subtracted, and the thumbunt must be regulated until the balance beam remains horizontal and the speed is as desired. The work absorbed by the brake is then

$$W = P\,2\pi R\,n;\ \text{or, more accurately, } W = P\frac{R}{r}2\pi r' n,$$

where $r'$ is the radius of pulley C. By using the latter formula, the error due to any slight inequality between $r$ and $r'$ is eliminated.

## THE CRUTO INCANDESCENT LAMP.

In the reports upon the Munich Electrical Exhibition Herr Goetz gave certain particulars relating to this lamp, but expressed the opinion that more extensive trials would be necessary for forming a correct judgment of it than had then been made. He now contributes to the "Centralblatt für Electrotechnik" an account of experiments lately carried out by himself. These had for their object the determination of the resistance co-efficient for the range of temperature from 18·8° to 98·8°C., the determination of the resistance at various stages of incandescence, and, above all, the connection between the electrical work expended and the intensity of the light. It appeared that the deportment of the examples with which the experiments were made was not uniform, and that the glowing filament of the Cruto lamp, which it appears consists of a combination of carbon and platinum, in respect of the change of resistance with increasing temperature sometimes approaches the character of platinum and sometimes of carbon.

The measurements of the resistances gave the following results in quicksilver units:—

| Lamp. | Temperature T = 18·8°C. | Temperature T = 98·8°C. |
|---|---|---|
| No. 1 | $W_0 = 22{\cdot}2\ Q{\cdot}U$ | $W = 24{\cdot}1\ Q{\cdot}U$ |
| No. 3 | $W_0 = 60{\cdot}5\ Q{\cdot}U$ | $W = 59{\cdot}3\ Q{\cdot}U$ |
| No. 4 | $W_0 = 97{\cdot}6\ Q{\cdot}U$ | $W = 94{\cdot}5\ Q{\cdot}U$ |

Using the formula $W = W_0 (1 + a\,t)$ the resistance co-efficient $a$ is found to be

For No. 1 lamp $a = +\ {\cdot}00107$
„ 3 „ $a = -\ {\cdot}00025$
„ 4 „ $a = -\ {\cdot}00040$.

For a pure carbon filament of a Swan lamp $a$ was found to have the value $-\ {\cdot}00071$, and for pure platinum the value is $+\ {\cdot}00200$, so that a comparison of the above values of $a$ in the Cruto lamps shows that the quantity of platinum in the filaments is in any case small, but is greatest in No. 1 lamp and least in No. 4. Another outcome of these experiments is that the resistance of the Cruto lamp during incandescence continually decreases. For instance, in No. 3 lamp, after two hours of incandescence, the resistance fell from 60·5 to 33·5 mercury units (both results applying at the same external temperature), and this without the relation between the light and the power changing. It is clear that this peculiarity, which exists moreover in all incandescent lamps which have not been subjected to incandescence, can only continue to a certain point, at which the resistance will then remain constant.

The resistance and powers were determined indirectly by direct measurements of the potential at the terminals and the current. The latter was determined by a tangent reflecting galvanometer of 19·546 centimetres diameter of two windings, the horizontal magnetic force being taken at ·2040 C.-G.-S. To determine the potential at the terminals one was connected to the earth, and the other to a cup of mercury. A condenser had one end connected to the earth, and the other with the mercury. The potential was determined by disconnecting it from this latter, and discharging to earth through a galvanometer the first elongations of which were observed. The sine of half this elongation was held to be proportional to the potential, as the condenser was considered to undergo complete discharge instantaneously. The co-efficient for this galvanometer was determined by using nine Daniell cells, each of which was assumed to have a potential of 1·106 volt. The current C and potential P being thus determined by observation, the resistance W and power A follow from the formulæ

$$W = \frac{P}{C}. \qquad A = P\,C.$$

For measuring the intensity of light a Bunsen photometer and ordinary stearine candles were used. As the main object was the dependence of the light on the power employed, it was not necessary to employ more precise sources of light; and, for the same reason, the intensity was only measured in one normal position. The following are the results of experiments on No. 2 lamp:—

CRUTO LAMP, No. 2.

| Experiment. | Terminal tension in Volts. | Current in Amperes. | Power in Volt-Amperes. | Power in Secmkgs. | Resistance in Ohms. | Light in stearine candles. |
|---|---|---|---|---|---|---|
| 1 | 5·69 | 0·160 | 0·909 | 0·093 | 35·6 | — |
| 2 | 11·34 | 0·294 | 3·339 | 0·340 | 38·5 | — |
| 3 | 22·17 | 0·539 | 11·944 | 1·217 | 41·1 | 1·2 |
| 4 | 25·52 | 0·611 | 15·602 | 1·591 | 41·7 | 2·3 |
| 5 | 27·33 | 0·644 | 17·595 | 1·793 | 42·5 | 3·3 |
| 6 | 29·05 | 0·681 | 19·774 | 2·016 | 42·7 | 4·4 |
| 7 | 30·99 | 0·710 | 21·998 | 2·242 | 43·5 | 5·85 |
| 8 | 32·29 | 0·742 | 23·949 | 2·441 | 43·5 | 7·2 |
| 9 | 34·01 | 0·772 | 26·261 | 2·676 | 44·0 | 9·2 |
| 10 | 35·78 | 0·801 | 28·658 | 2·921 | 44·7 | 11·8 |
| 11 | 37·47 | 0·817 | 30·634 | 3·122 | 45·8 | 15·7 |

It will be observed that the resistance of this lamp increased with the temperature, which gives the filament an analogy with platinum wire. The following table gives the results of trials under similar circumstances of a small Swan lamp:—

SMALL SWAN LAMP.

| Experiment. | Terminal tension in Volts. | Current in Amperes. | Power in Volt-Amperes. | Power in Secmkgs. | Resistance in Ohms. | Light in stearine candles. |
|---|---|---|---|---|---|---|
| 1 | 30·762 | 0·804 | 24·723 | 2·520 | 38·3 | 0·8 |
| 2 | 33·517 | 0·887 | 29·743 | 3·032 | 37·8 | 1·45 |
| 3 | 36·055 | 0·960 | 34·613 | 3·528 | 37·5 | 2·4 |
| 4 | 37·060 | 1·056 | 39·142 | 3·990 | 35·1 | 3·6 |
| 5 | 40·330 | 1·103 | 44·472 | 4·533 | 36·6 | 5·8 |
| 6 | 41·343 | 1·134 | 46·883 | 4·779 | 36·5 | 7·05 |
| 7 | 42·436 | 1·175 | 49·871 | 5·084 | 36·1 | 8·8 |
| 8 | 43·562 | 1·229 | 53·537 | 5·457 | 35·5 | 11·1 |
| 9 | 44·000 | 1·268 | 55·792 | 5·687 | 34·9 | 12·5 |
| 10 | 46·251 | 1·327 | 61·375 | 6·256 | 34·8 | 16·4 |

Since the reduction factor which should be used to deduce the average intensity from that in the normal position is nearly the same in the two lamps, Cruto and Swan, the above tables enable a fair comparison between the performances of the two lamps to be made. If these results are plotted a glance on the diagram will suffice to show how far in point of economy the Cruto lamp distances the Swan lamp. For instance, a light of 15 to 16 candles requires under the former system about half the power necessary under the latter.

In the Munich reports a simple formula was given as the law connecting the intensity of light with the power, which was found to agree with the observed values. This formula was $L = a\,A^3$, where $a$ is constant, and it was remarked that with the sole exception of the Cruto lamp the probable error was smaller with this formula than with either $L = a\,A^2$ or $L = a\,A^4$. The curves of this lamp showed variations from the formula of 10 and 12 per cent., and the equation

$$L = a\,A + b\,A^2,$$

where $a$ and $b$ are two constants, is found to be much more nearly satisfied by the quantities determined by experiment. Like the formula in the Munich reports this is entirely empirical, and it must therefore not be expected that for all values of the power (especially small values) the observed and calculated intensities of light should exactly coincide, but within the usual limits of these quantities the above equation serves very completely to represent the actual circumstances.

For the sake of comparison the small Swan lamp No. 1 of the Munich Reports has been submitted to a formula of this

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.
Digitized by Google

form, and in the following table the results of the two formulæ are comprised with those of observation :—

$a = \cdot000110$. $a = -\cdot2444$. $b = +\cdot1022$.

| $L = 0\cdot000110\ A^3$ Calculated. | Observed. | $L = -0\cdot2444\ A + 0\cdot1022\ A^2$ Calculated. |
|---|---|---|
| 4·202 | 4·571 | 3·360 |
| 6·132 | 5·575 | 5·119 |
| 7·980 | 7·536 | 7·536 |
| 10·118 | 11·101[1]) | 9·792 |
| 15·448 | 14·909 | 14·909 |
| 31·446 | 28·103 | 28·114 |

([1]) There is reason to believe that an error of about 1·1 candles has entered here.

For the small Swan lamp examined by Herr Goetz,

$a = -\cdot2184$, $b = \cdot7933$,

and the equation is

$$L = -\cdot2184\ A + \cdot7933\ A^2.$$

The following table shows the comparison between values deduced from this, and those deduced from the plotted curve :—

| A | L Calculated. | L From the curve. |
|---|---|---|
| 30·0 | 0·6 | 1·5 |
| 35 0 | 2·1 | 2·5 |
| 39·142 | 3·6 | 3·6 |
| 45·0 | 6·23 | 6·1 |
| 50·0 | 8·91 | 8·9 |
| 55·792 | 12·5 | 12·5 |
| 60·0 | 15·46 | 15·46 |

This shows that the curve is sufficiently satisfied by the equation, that is to say, the intensity of light in a Swan lamp follows the parabolic law when compared with the power.

The relation between the power and the light in a Cruto lamp follows the same law, which in the case of No. 2 lamp is given by the equation :—

$$L = -\cdot167\ A + \cdot197\ A^2,$$

which is shown to correspond with practical results by the table:

Cruto Lamp No. 2.

| A | L Calculated. | L From the Curve. |
|---|---|---|
| 12·0 | 0·83 | 1·2 |
| 15·0 | 1·92 | 2·1 |
| 18·0 | 3·47 | 3·5 |
| 19·774 | 4·40 | 4·4 |
| 22·0 | 5·87 | 5·87 |
| 24·0 | 7·29 | 7·29 |
| 26·0 | 8·97 | 8·97 |
| 28·0 | 10·77 | 10·8 |
| 29·0 | 11·73 | 12·3 |
| 30·0 | 12·72 | 14·1 |

No. 3 lamp gives results rather under those of lamp No. 2, as will be seen by the following table :—

Cruto Lamp No. 3.

| Experiment. | Terminal tension in Volts. | Current in Amperes. | Power in Volt-Amperes. | Power in Secmkgs. | Resistance in Ohms. | Light in stearine candles. |
|---|---|---|---|---|---|---|
| 1 | 25·497 | 0·5197 | 13·251 | 1·351 | 49·1 | 1·4 |
| 2 | 28·66 | 0·5980 | 17·126 | 1·746 | 47·9 | 2·6 |
| 3 | 30·33 | 0·647 | 19·621 | 2·000 | 46·9 | 3·5 |
| 4 | 31·85 | 0·705 | 22·454 | 2·289 | 45·2 | 4·8 |
| 5 | 33·31 | 0·777 | 25·873 | 2·637 | 42·9 | 7·4 |
| 6 | 34·76 | 0·827 | 28·740 | 2·930 | 42·0 | 10·5 |
| 7 | 36·33 | 0·886 | 32·209 | 3·283 | 41·0 | 17·0 |

The resistance decreases with increase of temperature, as had already been determined at low temperatures for this lamp.

The equation for this lamp is :—

$$L = -\cdot3277\ A + \cdot2411\ A^2,$$

and the correspondence between this formula and the results of trial are exhibited below :—

Cruto Lamp No. 3.

| A | L Calculated. | L From the Curve. |
|---|---|---|
| 20·0 | 3·1 | 3·65 |
| 22·45 | 4·8 | 4·8 |
| 23·0 | 5·22 | 5·2 |
| 24·0 | 6·01 | 5·9 |
| 25·0 | 6·88 | 6·7 |
| 26·0 | 7·78 | 7·5 |
| 28·0 | 9·72 | 9·6 |
| 28·74 | 10·5 | 10·5 |
| 30·0 | 11·87 | 12·4 |
| 31·0 | 13·02 | 14·2 |
| 32·0 | 14·20 | 16·5 |

In order to determine if the continual change in resistance mentioned above makes a difference in the relation between the light and the power another series of experiments was made with the Cruto lamp No. 3, with the results shown in the next table :—

| Experiment. | Terminal tension in Volts. | Current in Amperes. | Power in Volt-Amperes. | Resistance in Ohms. | Light in stearine candles. |
|---|---|---|---|---|---|
| 1 | 24·48 | 0·681 | 16·66 | 36·5 | 2·45 |
| 2 | 26·00 | 0·726 | 18·88 | 35·8 | 3·4 |
| 3 | 27·60 | 0·763 | 21·05 | 36·2 | 4·1 |
| 4 | 29·05 | 0·798 | 23·18 | 36·4 | 5·3 |
| 5 | 30·77 | 0·831 | 27·90 | 37·0 | 9·8 |

The light curve when plotted is found to coincide with the former one for this lamp, that is to say, the changing resistance has no influence upon the relation of the power to the light. This series of experiments was unfortunately terminated by the platinum-carbon filament becoming detached, a *contretemps* due to the faulty mode in which it had been fastened in the lamp.

From these results a fair idea of the performance of the Cruto lamp can be formed. If it should turn out that the length of life of these lamps is as great as that of the Swan lamp and others, the excellent economy in power for the same light displayed by the Cruto lamp must distinguish it as an important step forward in incandescent lighting.

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 83).

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

#### HISTORY IN RELATION TO TELEGRAPHY.

Around the magnet. Faraday
Is sure that Volta's lightnings play,
But how to draw them from the wire?
He took a lesson from the heart—
'Tis when we meet—'tis when we part
Breaks forth the electric fire.

*Impromptu*, by Herbert Mayo,
in *Blackwood's Magazine*.

Early in the present century philosophers thought they saw an analogy between magnetism and galvanism in a phenomenon,

Digitized by Google

which we find thus referred to in Lehot's "Observations sur le Galvanisme et le Magnètisme" (Paris, *Circa*, 1806, 8vo, 8 pp.): —"It has long been known that the two wires which terminate a pile attract one another, and, after contact, adhere like two magnets. This attraction between the two wires, one of which receives, and the other loses, the galvanic fluid, differs essentially from electrical attraction, as Ritter observed, since it is not followed by a repulsion after contact, but continues as long as the chain is closed" (Note on page 4).*

In the same spirit of enquiry Desormes and Hatchette, in 1805, tried to ascertain the direction which a voltaic pile, when freely suspended horizontally, would take. The pile, "composed of 1,480 thin plates of copper tinned with zinc, of the diameter of a five-franc piece," was placed upon a boat, which floated on the water of a large vat; but it assumed no determinate direction, although "a magnetised steel bar, of a weight nearly equal to that of the pile, and placed like it upon the boat, would turn, after some oscillations, into the magnetic meridian (*Philosophical Magazine* for 1821, Vol. 57, p. 43).

The honour of the discovery of the much-sought for connection between electricity and magnetism has often, in the last fifty years, been claimed for Romagnosi, an Italian writer who is justly esteemed for his works on history, law, and political philosophy. Govi†, however, in 1869, showed in the clearest manner possible the absurdity of this claim; but, notwithstanding, it has been again put forward, and this time by no less an authority than Dr. Tommasi, of Paris, in a recent number of *Cosmos les Mondes* (June 30, 1883).

Dr. Tommasi, in republishing Romagnosi's experiment, asks the following questions, which he submits, in particular, to the managing committee of the Vienna Exhibition, in the hope that they may be brought before electricians:—

"Is it to Oersted, or to Romagnosi, that we should ascribe the merit of having first observed the deviation of the magnetic needle by the action of the galvanic current?

"Had Oersted any knowledge of the experiment of Romagnosi when he published his discovery of electro-magnetism?‡

"Have any other *savants* taken part in this discovery?"

Now, we should have thought that after the admirable *exposé* of Govi, to which we have just referred, no electrician would seriously put to himself these questions. But it appears that our Paris *confrère* does so, although, if he had only read carefully the facts on which he bases them, he would perceive that they have no relation whatever to electro-magnetic action, but are simply effects of ordinary electrical attraction and repulsion brought about by the static charge which is always accumulated at the poles of a strong voltaic *pile*—the form of battery used in Romagnosi's experiments, and which, as is well known, exhibits this phenomenon in a far more exalted degree than the ordinary cell arrangement.

We cannot establish better the correctness of our conclusions than by quoting in full the recital of Romagnosi's experiment, which originally appeared in the *Gazzetta di Trento*, of August 3, 1802,:§—

"Article on Galvanism.

"The Counsellor, Gian Domenico de Romagnosi, of this city, known to the republic of letters by his learned productions, hastens to communicate to the Physicists of Europe an experiment showing the action of the galvanic fluid on magnetism.

"Having constructed a voltaic pile, of thin discs of copper and zinc, separated by flannel soaked in a solution of sal-ammoniac, he attached to one of the poles one end of a silver chain, the other end of which passed through a short glass tube, and terminated in a silver knob. This being done, he took an ordinary compass-box, placed it on a glass stand, removed its glass cover, and touched one end of the needle with the silver knob, which he took care to hold by its glass envelope. After a few seconds' contact, the needle was observed to take up a new position, where it remained, even after the removal of the knob. A fresh application of the knob caused a still further deflection of the needle, which was always observed to remain in the position to which it was last deflected, as if its polarity were altogether destroyed.

"In order to restore this polarity, Romagnosi took the compass-box between his fingers and thumbs, and held it steadily for some seconds. The needle then returned to its original position, not all at once, but little by little, advancing like the minute or seconds hand of a clock.

"These experiments were made in the month of May, and repeated in the presence of a few spectators, when the effect was obtained without trouble and at a very sensible distance."

Here it will be seen that Romagnosi uses only *one* pole of the pile, and *never speaks of the circuit being closed*—facts which show that his experiment has no resemblance to that of Oersted.

The effects which he describes are, moreover, easily explainable on another hypothesis. The compass needle, we may imagine, received a charge of static electricity by contact with the charged pole of the pile. Being insulated it could not part with this charge, and, consequently, as soon as it had attained the same potential as the voltaic pole, mutual repulsion ensued. As the needle belonged to "an ordinary compass-box," we may assume it was neither strongly magnetised, nor delicately suspended. Friction at the point of support, then, might more than counterbalance the directive force of the earth, and so the needle would always remain in the position to which it had been last repelled.

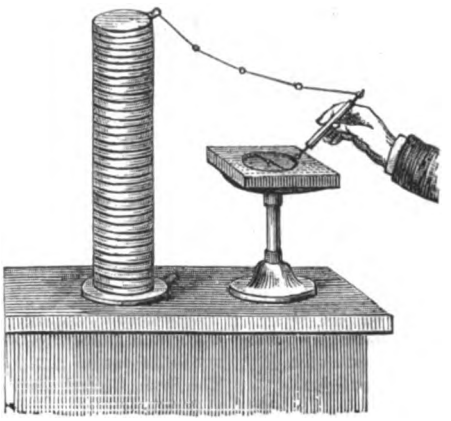

FIG. 1.—Romagnosi's Experiment, according to Govi. Copied by kind permission of Mr. Latimer Clark.

The "restoration of polarity," or the bringing back of the needle to the magnetic meridian, by merely holding the compass-box steadily between the fingers and thumbs, although savouring of legerdemain, was really due to a "simple turn of the wrist." Romagnosi may have imagined that he held the compass-box *steadily*, but there can be no doubt that his hands suffered a slight and imperceptible tremor, which, aided by the directive force of terrestrial magnetism, sufficed to shake the needle into a north and south position.

Another, and to us convincing, argument against the supposition that Romagnosi had any share in the discovery of electro-magnetism is that he himself never claimed any, although he lived down to the year 1835, or fifteen years after the announcement of the Danish philosopher.*

To the same category belongs the contrivance of Schweigger, which is described in Gehlen's *Journal für die Chemie und Physik*, for 1808 (Vol. VII., pp. 206-8), and on the strength of which a recent writer† says that the celebrated inventor of the galvanometer ought also to be considered as the discoverer of electro-magnetism. There is no ground whatever for this statement. Schweigger's paper, which is headed "On the Employment of the Magnetic Force for Measuring the Electrical," simply describes an electroscope for indicating the attraction and repulsion of ordinary, or frictional, electricity, and which he used as a substitute for the torsion electrometer of Coulomb. It consisted of a magnetic needle, armed at each end with a brass knob, and mounted on a pivot, as in an ordinary compass.

* This discovery appears to have been made independently, and about the same time, by Gautherot, in 1801 (*Philosophical Magazine*, for 1828, Vol. IV., p. 458); by Laplace; and by Biot (*Journal de Physique, de Chimie*, &c., for 1801, Vol. LIII., p. 266). The latter made the further very acute observation that, if the wires be attached to plates of metal, and these plates be approached by their *edges*, they will attract one another; while if approached by their *faces* no action whatever takes place.

For other interesting experiments of this kind see Nicholson's *Journal*, for 1804, Vol. VII., p. 304.

† "Romagnosi e l'Elettro-Magnetismo," Turin, 1869.

‡ Dr. Hamel, for one, thought he had, and tries to prove it in his "Historical Account," &c., of 1859 (pp. 37-9 of W. F. Cooke's reprint).

§ Our translation is made from the reprint at page 8 of Govi's "Romagnosi e l'Elettro-Magnetismo."

* For some very interesting experiments of this kind see Van Mons' *Journal de Chimie*, for Jan. 1803, page 52; also Nicholson's *Journal*, Vol. VII., p. 304.

## THE NEW PATENTS ACT.

Whatever may be the private opinion of experts on the working prospects of the new Patents Act there appears to be a general disposition to accept the measure uncomplainingly, to make the best of its good points, and to hope that its bad points will be practically disregarded or speedily repealed. Knowing how rarely an Act gets amended after being put into operation, we do not ourselves expect any relief in the last-named direction. Many people think the machinery of the new Act unworkable; but when the reputation of a public department is at stake it is unlikely that failure on this account will be permitted. The machinery will be made to work somehow, and probably the rules of procedure which the Board of Trade are empowered to draw up will be made to cover any defects discovered in the Act itself when it has had a fair trial. In a recently published pamphlet explaining the scope and bearings of the Act Mr. A. V. Newton alleges that the labour devolved upon the Chief Comptroller is incalculable and overwhelming. This may be so, and indeed it is obvious he cannot perform the duties assigned to him. But there is a way out of that difficulty, familiar to all public offices, namely, the calling in of adequate assistance, and the relegation of superabundant duties to subordinates. It is merely a question of money, and as the estimates for the office of the comptroller are not unalterable, they can be framed so as to cover all payment for help proved to be indispensable.

The real question it seems to us will be, not whether the comptroller's duties are too heavy for any one man either to perform or to see that others perform, but whether the performance is worth anything when it is done. It is greatly to be feared that the advantages of the new system will prove to be illusory. Except in the matter of original outlay the patentee gains nothing at the hands of the examiners; and even as regards expense, it has been argued with fair show of reason that it is no boon to induce a greater number of people to expend small sums for which no return is assured. In other words, the large increase of applicants for patents will only swell the number of the disappointed. The heavier fees of the old Act, if they assured nothing, did at least check the growth of competitors, imitators, and infringers; and they also limited the applicants to those who had invented something on which it was worth risking a considerable sum. Disappointments, though not rare, were therefore restricted in number, whereas at the expiration of the present year disappointments will probably be the rule. There may be something said for the changes on the grounds of public expediency; but it is not an act of kindness to invite and even encourage poor men to spend their pounds on supposed inventions which richer men would not risk even their sixpences upon. It is possible to get protection for four years under the new law at a cost of only four pounds. For such limited protection as this sum will cover there may be cases where the inventor will profit by the arrangement. Experience alone will determine how many of such cases are likely to arise. But for inventions requiring protection during the longer period of fourteen years, the charges remain almost unaltered, and are merely deferred. It comes to this, therefore, that what we have done is to encourage a lot of patent experiments and speculations under the mistaken notion that they are cheaper than they formerly were, whereas they are only of shorter duration, the long patents being almost as dear as ever.

Like many other recent reforms involving a seeming reduction of charges, this one was not called for by the people most interested in the matter. Its popular element is an experiment, the result of which cannot be predicted at present; but for the class of investigators and experimentalists to whom we have hitherto been indebted for our most useful inventions this new Patent Act will be an unmixed vexation. It will vastly increase the difficulties of securing protection for a substantial invention in the face of a host of small intruders, incompetent to work out an idea thoroughly, but, under the new regulations, quite competent to block the path of superior men. From one point of view the framers of the Act seem to have aimed a blow at what they would call the monopoly of monopolists, that is to say, the monopoly in inventions possessed by those who alone can afford to pay for it. But if this was their object, they have attained it at the expense of the public, who will henceforward be burdened with a vast enlargement of the area for monopoly without any compensating advantage. It is certain that a great many more trivial things will now be patented; it is by no means certain that important patents will increase in number.

Indeed, for reasons already hinted at, it is probable that many good patents will be shipwrecked on the shoals of the bad ones. One of the many and remarkable duties assigned to the examiners of the new Patent Office will be to report when an application for a patent is anticipated by an appli-

Digitized by Google

cation already in the office. It may be feared that when any notable discovery is in the air, and its practical development is being worked out in the laboratory, there will be no lack of applications already "in the office" sufficiently vague, yet sufficiently comprehensive to "anticipate" anything and everything, while too premature and unpractical to be of use to anybody. The decision of the examiners on such points, it is true, is subject to appeal; but as the official legal advisers are also the official appellate judges, obviously they will all work together to uphold the original official opinion. Even should the specification succeed in passing this ordeal of the examiners, it is then put before the public, who are virtually invited to pick holes in it; in other words to lodge objections which the examiners are bound to weigh and consider before issuing the patent. All this might be tolerable if the patentee were now secured in what he has obtained. But that is by no means the case; he is liable to petition for revocation of his patent much the same as heretofore, his risk under this head being diminished only by the circumstance that as he has already gone through so much there is not a great deal left for him to endure. His one consolation is that during the first four years of the patent the fees will be reduced. But fees, as is well known, constitute a very small fraction of the expense incurred in working up a patent and putting it on the market.

In several respects the effect of the Act will greatly depend on the spirit in which it is administered. Mr. Newton in the pamphlet to which we have referred speaks strongly as to this, remarking on the process of examination that the most mischievous consequences may be confidently predicted; but adding that it may be hoped that this part of the Act will fall into disuetude. The same remark would apply to the stipulation that each specification shall contain but one invention only. This may be worked in a manner very costly to the applicant, for it often happens that one invention is of no earthly use without a second invention to render it servicable. Separately these two inventions, constituting, perhaps, a new product and a new process of manufacture, are valueless, and it would be manifestly unjust as well as impolitic to interpret the Act too rigidly so as to compel two patents to be taken out for them. Much, it may be hoped, in these and other matters, which at present look mischievous, will be toned down by the practical good sense of those to whom the working of the Act will be entrusted. It cannot be repealed, but it can and ought to be watched very carefully.

## CORRESPONDENCE.

### WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: If you will allow me I will ask through your paper of those electricians who may be interested in the matter an explanation of Mr. Latimer Clark's definition of electricity, a substance, like water or gas, having a veritable existence, and although easily convertible into heat, in other respects indestructible.

If electricity is a substance, like water or gas, having a veritable existence, it must also be material.

Now, material things cannot be convertible into heat, which is acknowledged generally to be immaterial, merely depending upon the existence and conditions of other bodies with their changes. Heat is abstract, merely vibration.

If the "substance" electricity be turned into heat, it is natural to suppose under certain conditions it could be turned back again into electricity.

Now, how can a mere vibration be changed into a material "verily existing substance?"

Heat dies. Where is the heat of the once so fiery moon? But no substance, like gas or water, having a veritable existence dies. It can only change. But it has been proved that electricity can be changed into heat. Therefore I maintain that electricity cannot be a "substance, like water or gas, having a veritable existence."

Every atom vibrates from the centre outwards, that is to say, alternately swells and diminishes.

Of course the maximum disturbance of particles would then be on the surface, or, to be more exact, the vibration of everything on the inside is opposite to the vibration of everything on the outside.

Some atoms vibrate in time with other atoms, that is to say, one atom swells while the other diminishes. Some atoms work out of time with other atoms, that is to say swell when other atoms swell. Atoms working out of time with other atoms collide actually, or through the medium of air or æther which surrounds them, and thereby are repelled from those atoms.

But there is no reason why atoms working in time with each other should not fall together, which as they are repelled from all other atoms they are liable to do. Here, then, is an explanation of the force of gravity as well as of electricity.

Let *a* be a pith ball, *b* a positively charged body. A positively charged body means a body with the same vibration as negative charged bodies. *a* having the same vibration as *b*, or the vibration of *b* being nearer *a*'s vibration than that of any other body, *a* flies to it. Having once reached it, it is made one with it, and vibrates all over its surface with the same vibrations as *b*, therefore it has now become an atom of the same vibration as all other atoms in the neighbourhood of *b* likewise attracted by *b*'s manner of vibration. Now, therefore, it is liable to fly to all other atoms, but does not because it moves in time with *b*'s surface throughout the whole of its mass. But if it rolls or moves slightly round on *b*'s surface, its surface vibration becomes opposed to that of *b*, and consequently it flies from *b*.

I dare say all other experiments of a like nature could be explained in this manner, always remembering that there is no real space, everything containing air or æther throughout the whole world.

Sound I should take to be whole atoms knocking against whole atoms, and thus transmitting the motion.

Light I should take to be the same sort of vibration as electricity, but more violent. If very violent indeed at any point the electrical vibration or the rapid swelling and diminishing of particles is converted into the concussion of whole atoms, thereby producing sound.—Yours, &c.,

ARTHUR H. BENGOUGH.

Eastern Ex. Tel. Company.

### MAGNETO ELECTRIC INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Knowing the reputation and wide circulation of your admirable journal, *The Electrician*, and recognising its great utility as a source of information in questions connected with the science of electricity, at a time when its usefulness is specially called for, I take the liberty of asking through its medium the explanation of a phenomenon which has long perplexed me, and for which I can find no sufficiently satisfactory explanation in any text book of the science with which I am acquainted. If yourself or any of your correspondents would either clear the point or suggest an explanation, I could appreciate the favour at its proper estimate.

When an armature and its enveloping coil of covered wire rotate before the poles of a permanent horseshoe or parallel magnet, it is well known that, as the armature and coil are approaching the north pole, an induced current is generated in the coil, running from left to right, or in an opposite

Digitized by Google

direction to the amperean currents circulating around the north pole of the permanent magnet itself. The iron core is also magnetised on its approach, having a south pole induced in that portion in proximity to the north pole of the permanent magnet, and a north pole at the other extremity. Now, to what influence is the current generated in the coil to be ascribed? Is it to that of the north pole of the permanent magnet alone, or to the magnetism induced in the iron core alone, or to both? If the current developed in the coil be due to the magnetism of the core alone, it is *primâ facie* difficult to conceive why it should not run from right to left, or as if it were under the influence of south polarity, since both poles are necessarily co-existent in the core or armature, owing to induction.

The explanation which suggests itself to me is that as the armature approaches the north pole the inductive action of that pole upon it has the same effect as if the north pole of a magnet were suddenly pushed up through the coil—a movement which would send the induced current in the observed direction from left to right. And further, that the north pole of the permanent magnet acts in conjunction with the magnetic influence of the core or armature, and thereby enforces or supplements its action.

Should this explanation be right, I would be glad to have it confirmed on the authority of some of your correspondents, or, if erroneous, the right explanation offered.—Yours, &c.,

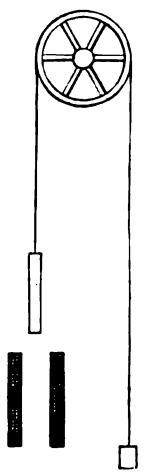
Newtownards, 8th December, 1883. JOHN DE VANE.

## ENDLESS CHAIN DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am sorry to have to contradict the result of Mr. Voice's experiment, as well as his theoretical reasonings.

In the first place, I have tried the experiment with the solenoid and the iron core as described by Mr. Voice, but in no case did the iron core go out from the other side of the solenoid, although it was introduced in the solenoid by the hand with such an impulsion that, with open circuit, it should have overcome the friction and passed through. To render the experiment more conclusive, I have suspended the iron core to one end of the thread of Atwood's machine, while the other end was charged with the necessary load to obtain equilibrium, as shown by the sketch. The solenoid was fixed with its axis in the same vertical line as the iron core. The solenoid was 12 cent. long, 9 cent. in external, and 4 cent. in internal diameter, and wound with thick wire; the core was 16 cent. long, and 1 cent. in diameter. If the current of a small Gramme machine with permanent magnetic field was sent through the solenoid, and the iron core allowed to gradually approach it, at a certain point it was attracted by the solenoid; but, although the friction of the system was extremely small, it did not show the least tendency to pass out through the solenoid; on the contrary, after some rapid oscillations it stopped in the middle of it. By adding or taking away some weights from the counterpoise, the equilibrium was broken, and, the Gramme machine being at rest, the iron core passed through the solenoid with accelerated velocity; but if the Gramme machine was put in action, the initial velocity of the core being not too great, it was stopped by the solenoid.



This experiment clearly demonstrates that "*the solenoid acts like a brake on the iron core, and not like a motor*," as I pointed out in my last letter printed in your issue of Nov. 24th. But at that time having only some doubts as to the correctness of Mr. Voice's experiment, I could only express my opinion with timidity, and I was right to be puzzled by the contradiction between the theory and the experiment of an able man. Now that I am fully convinced that the error is in Mr. Voice's experiment, I can freely refer the reader to my last letter for the explanation of my own.

As far as the theory of the action of a solenoid is concerned I find the ideas of Mr. Voice somewhat confused, and I have no doubt that if he considered the lines of force instead of the polarity, he would rather be led to forsake his belief in the two opposite polarities he supposes in a solenoid. If the polarity of an iron rod put in the interior of a solenoid is opposite to that of an exterior one, this is only because, the lines of magnetic force being closed as rings, they must run outside the solenoid in the opposite direction to that they have in the interior.

There is certainly a capital difference between the magnetic field of a solenoid and that of a permanent magnet; but it is not the same as that pointed out by Mr. Voice. The true difference is this:—*In the field of a solenoid the lines of force can entirely flow through the external space occupied by the air, or by every other non-magnetic body; whilst in the field of a permanent magnet every line of force must necessarily pass for a certain length of its path through a certain part of the body of the magnet.*

In the instances referred to by Mr. Voice on closed magnetic rings, practically all the lines of force flow through magnetic bodies; but this does not prevent them from acting inductively on the crossed solenoids. So, if we suppose that the air contained in the solenoid is instantaneously transformed into solid iron completing a closed magnetic ring, induction will certainly arise in the solenoid, because most part of the lines of force before existing *outside* the magnetic bodies *cross the solenoid* in order to rejoin the path of the closed magnetic ring.

The Count Du Moncel in his "Exposé des Applications de l'Electricité," Vol. II., pp. 206—215, Third Edition, dedicates several pages to the description of "*cette catégorie d'appareils* (qui) *dérive des réactions produites par le passage d'une armature de fer deux devant les poles d'un aimant persistant muni de bobines d'enduction.* He describes the machines of Breton Frères, Duchenne de Boulogne, Wheatstone, Dujardin, Breguet, and Wilde. In the "Traité d'Electricité et de Magnetisme," de M. M. Becquerel, Vol III., pp. 237 and 238, the machines of Page and Breton are described. The Page machine is also described in the "Cours de Physique de l'Ecole Politechnique," de M. Jamin, Vol. III., p. 308, Second Edition.—Yours, &c.,

Padova, Dec. 8, 1883. G. B. ERMACORA (Dr.).

## BATTERY ENERGY AND ZINC CONSUMPTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In this age of innovation and improvement, we have several battery claimants for prodigies of value, where it is alleged that the consumption of zinc is greatly reduced for a given energy or horse-power for lighting and other purposes. But they are coldly met by professional authorities, who are eloquent as to the comparative cost of zinc and coal; and when reminded as to the difference between a one-volt or a two-volt battery, they readily retort: Yes, you may have a doubly active cell, but it also implies a double consumption of zinc. Such, I take it, is the way these innovators are frowned upon; but is it just? Or is it the way steam navigation and gas lighting have been professionally repudiated?

I am purely disinterested, and wholly unconnected with any of these battery schemes; but I do maintain that a given amount of volt-amperes, watts, or horse-powers, may be obtained with half the consumption of zinc, as compared with a Daniell or one-volt battery.

I care not to go into dry figures in proof of this statement, because it must be evident to any electrician who choses to lay aside prejudice and preconception.

In a two-volt battery we have oxidation of zinc on one side and oxidation of hydrogen on the other, and both are factors in the production of increased energy and diminished internal resistance.

The statements of Mr. Ross must go for nothing while he refuses to publish his data, and the probability is great that he refers to the total energy of his battery, and not to the "economic yield" or lamp circuit.

Given a two-volt battery, and I can ensure 1,000 volt-

Digitized by Google

amperes in the external or lamp circuit, at a total cost of 1·391b. of zinc per hour; but what may be the cost of "oxidone" or other oxidant, and what may be the lasting power of the battery, that I must leave to those interested. It is true that we may buy cast-spelter wholesale at 2d. per lb.; but I do maintain that for plates of the right form and *quality* 3d. per lb. should be the lowest estimate. With the best zinc costing 4d. per unit of 1,000 volt-amperes, and not 2d. as promised by Mr. Ross, where the wholesale market price is 8½d. to 9d. per unit, it does seem that these innovators may have a fair field and considerable encouragement.

—Yours, &c. SAM. E. PHILLIPS, F.C.S.

## SEISMIC DISTURBANCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following theory with respect to the origin of "seismic disturbances" has for some time occupied my thoughts, and as I have seen more seemingly absurd ones advanced by scientific men, I venture to send this to you for insertion (if you consider it worthy).

A connection has been established between "seismic disturbances" and some of the magnetic disturbances that take place on the globe which none of the present earthquake theories can explain. If we suppose currents of electricity to be flowing round under the surface of the earth in the direction indicated by the magnetic needle at the surface (from E. toW. nearly) these currents would of necessity in some places meet with considerable resistance, rupturing the dielectic in places (causing the earth above to tremble), and in places heating the substance through which it is flowing, causing it to melt, expand, and flow out on the surface (causing volcanoes, &c.).

If such currents exist they must have a cause.

Now I consider the sun's light to be caused by currents circulating round it (how generated I am unable to say at present); these currents would induce currents in the planets, as they are continually cutting fresh lines of force, corresponding in the earth to the currents which I have supposed to be circulating round it.

If such is the case we should expect that the earth's daily and yearly motions influenced the magnetic needle in a more or less degree, which it really does, though a complete explanation of either would necessitate a complete knowledge of the magnetic field due to the sun and all the planets.

Also changes which occur in the sun, as for instance, spots and disturbances in the solar atmosphere, should not only influence the magnetic condition of the earth, but also that of the planets. Now, the earth's currents are so influenced we know from observation, and the planet Jupiter seems to be similarly affected, as his belts are disturbed at the very same time at which these disturbances occur. I account for the fact that the induced current shows itself at the surface in Jupiter and other similar planets, and not at the earth's surface, by the greater speed of rotation of the former. It has been urged by Proctor and others that the sun's corona is of the nature of a solar aurora, which is easily accounted for by this theory. I think, if the secular changes which occur in the earth's magnetism could be predicted by calculations from this theory, that it would be established beyond dispute.—Yours &c., R. P. F.

December 6th.

P.S.—I am afraid I have not been very clear in order to be as brief as possible.

## THE ELECTRIC LIGHT AT THE GAIETY THEATRE, GLASGOW.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Referring to the description of the lighting of this theatre with the electric light, we notice that it has been omitted altogether to state that the work was carried out entirely by the Jablochkoff Electric Light and Power Company, and as the result of the recent trial proved the installation to be throughout a perfect success, it may be interesting to your readers if we take this opportunity of stating how it was conducted. The installation consists of 280 incandescent lamps of 20 candle-power each, 3 Jablochkoff patent arc lamps of 800 candles, and 9 Jablochkoff patent arc lamps of 400 candle-power.

Around three tiers of the auditorium are placed 40 incandescents, in the pit 16, corridors and gallery have 12 lights, main entrance 30, the smoking, crush, and refreshment rooms employ 26, the dressing rooms, green room, and offices a further 16, while upon the stage are 40 as foot lights, with also 4 battens containing 24 lights each.

Three of the large type (800 c.-p.) of arc lamps are placed in the centre of ceiling, one in each of the four docks of the stage, and the remaining five are outside the theatre.

The motive power is obtained from two Marshall 16 horse-power engines of the semi-portable type, which drive one alternating Gramme dynamo machine, connected up for a quantity current to supply the incandescent lamps, and two Jablochkoff dynamos, size B, supplying the current to the arc lamps.

Arrangements are perfected whereby the lights in any circuit can be independently lowered or raised at pleasure.

We believe this is the first instance in this country of the lighting of a theatre by both arc and incandescent systems at once.—Yours, &c.

FRAS. R. REEVES, Secretary and Manager.

1, Great Winchester-street-buildings, Dec. 12, 1883.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In answer to your correspondent, "W.T. Farquhar's," question about his dynamo, I would say that I am having a small machine, with Siemens H armature, made, to light three 5 candle-power lamps, at 2,000 revolutions. If he does not mind waiting two, or at most three weeks I will then give him a full description of mine. Probably no one can find the mistake in his machine without first seeing it, as there are so many things to be taken into account in making a successful machine.—Yours, &c.,

W. HITCHCOCK.

## LES TÉLÉPHONES.

AGENCEMENT DES BUREAUX TELEPHONIQUES DANS LES GRANDS CENTRES — APPAREILS — CONSTRUCTION DES LIGNES ET EXPLOITATION—AUDITIONS TELEPHONIQUES MUSICALES FANFARE ADER—AVEC 43 FIGURES GRAVEES DANS LE TEXTE — PAR A. L. TERNANT. MARSEILLE, CHEZ L'AUTEUR, 62, BOULEVARD LONGCHAMP, ET LIBRAIRIE LAFFITTE, 1, BOULEVARD DU MUSEE. 1884.

(CONTINUED FROM PAGE 87.)

The double wire system has been adopted by the Société Générale on the recommendation of M. R. G. Brown, and consequently the ordinary American jackknife has had to be modified. The new commutator forming, so to speak, two simple jackknives back to back, it is necessary to first of all describe the simple jackknife, which is, moreover, still employed on single wire provincial lines.

The jackknife consists of a piece of copper (Fig. 3) of rectangular shape, fixed in its place by two screws. The first, L, terminates in a bolt, which serves both to fasten the jackknife and to insure the connection between the subscriber's wire and the metal of the commutator. The second screw, I, is connected with the wire of the indicator, which is put to earth. This bolt is always insulated from the metal of the jackknife, and is furnished with a little piece of metal which

Digitized by Google

projects upwards, but does not touch the metal anywhere. This piece of metal communicates with the end of a stiff spring, fastened by a screw at one end to the metal of the jackknife. This spring is brought into play by a pin attached to it, which penetrates the hole numbered 2 in Fig. 3. In the position shown in this figure the jackknife is ready for action. The line is connected with the indicator. If the subscriber calls by putting the current of his battery into

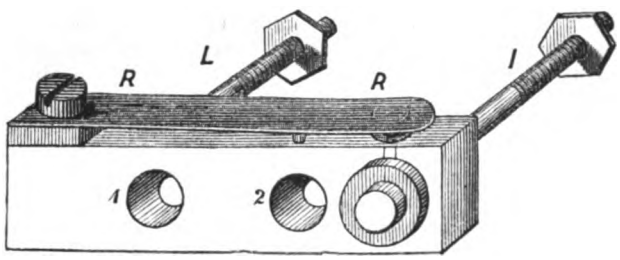


Fig. 3.—Simple Jackknife.

the circuit the indicator falls, a bell placed in the local indicator circuit rings, and the central office is warned. As will be seen, the jackknife has two holes, 1 and 2. The operator at once places in hole No. 2 a plug, to which is attached a flexible cord leading to the telephone. The plug lifts the pin fixed to the spring R, and thus breaks contact between the body of the jackknife and the indicator. In this way the indicator is cut out of the line and the telephone put in

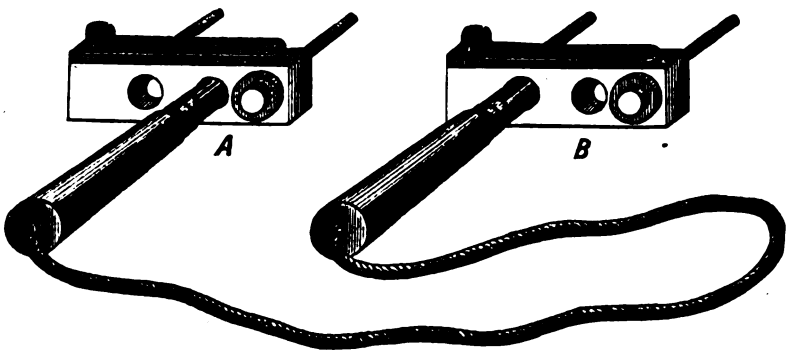

Fig. 4.—Connections between Two Jackknives.

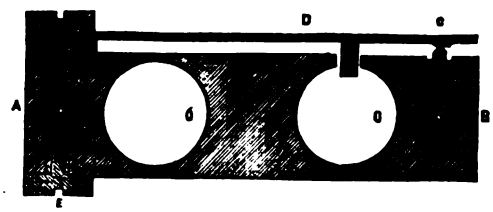
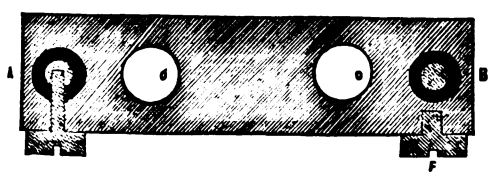
circuit instead. The operator then takes the instructions of the subscriber as to whom he wishes to speak with. To connect two jackknives (Fig. 4) use is made of a flexible cord with a plug at each end, which fit into



Front Plate.



Back Plate.

Fig. 6.—Showing Parts of Double Jackknife.

holes 1 and 2. If we wish to shunt circuit one of the indicators the corresponding plug is inserted in hole 1, the spring is not lifted, and the body of the jackknife, which forms part of the line circuit, is connected to the indicator and to earth. Experience has proved that there is no perceptible difference in the working of the telephone whether all shunts be suppressed or one of 300 ohms be introduced. Now, the two coils of the indicator form a circuit, the resistance of which is about 200 ohms. Other combinations are possible with the jackknife. Special call indicators can be used and introduced in the circuit of the subscribers who are talking. This is done by means of two flexible cords, one of which leads from jackknife A to the ingoing terminal of the indicator, and the other from the outgoing terminal of the indicator to jackknife B. The double jackknife used in the central office at Paris allows of this precise combination with but one apparatus. Fig. 5 gives a perspective front view of the instrument.

This double jackknife is the result of the united labour of MM. Lartigue, Brown, and Berthon. It is composed of two pieces of metal, placed back to back, and separated from one another by a thin ebonite plate. The front plate has two holes, which lead right through, and enable the jackknife to be fixed to the table by means of two bolts, which likewise lead to the two terminals of the indicator. Screw B in Fig. 6 is completely insulated from the two metal plates, except at the point C, where a small pin, screwed into it and insulated from the plate, enables connection to be established between C and spring D of the ordinary jackknife. The two plates are each in connection with one of the wires of the double line by the screws E F, and the indicator will remain in the circuit of this line so long as the spring makes contact between the front plate and the indicator. But it

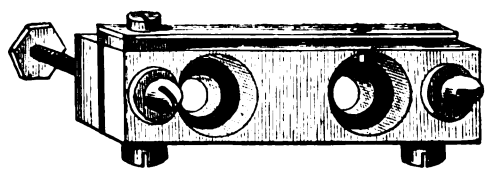


Fig. 5.—Double Jackknife.

will be cut out when the contact between C and D is interrupted by the introduction of a plug in the hole O. The

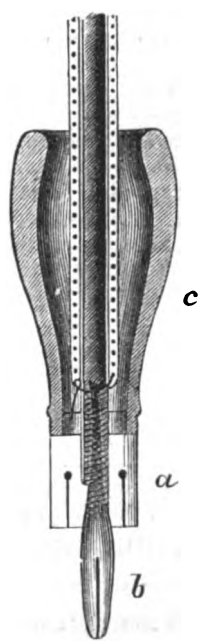

Fig. 7.—Plug.

Digitized by Google

plugs to be introduced in O and O′ both have double wires, and as shown in Fig. 7 the portion marked *a* is far larger than that marked *b*, both parts being carefully insulated from one another by ebonite *c*; each of them, moreover, is connected to one of the wires contained in the flexible cord. This latter is made as follows:—The central conductor is a wire wound corkscrew fashion, and covered with silk of a sufficient thickness to entirely insulate this wire from the second, which is wound over it, also in corkscrew fashion. A second covering of floss silk envelops the whole, which forms a very handy flexible cord. The central wire affords a passage for the solid part *b* of the split pin, which makes excellent contact with it, additionally secured by a bit of solder. The second wire is soldered to the round portion *a*, and the two parts of the pin are so made as to each, independently, make good contact when the whole is put into the holes O and O′ of the jackknife. When this is done the spring is lifted, and the wire of the indicator corresponding with the insulated point C is disconnected.

(TO BE CONTINUED.)

## ELPHINSTONE-VINCENT EIGHTY-LIGHT DYNAMO.

We this week illustrate an 80-light Elphinstone-Vincent dynamo. It will be seen from the engravings that the general arrangements of the parts in this machine differ somewhat from that of the larger machine illustrated in *The Electrician*, Vol. X., p. 233.

80-light Elphinstone-Vincent Machine.

FIG. 1.

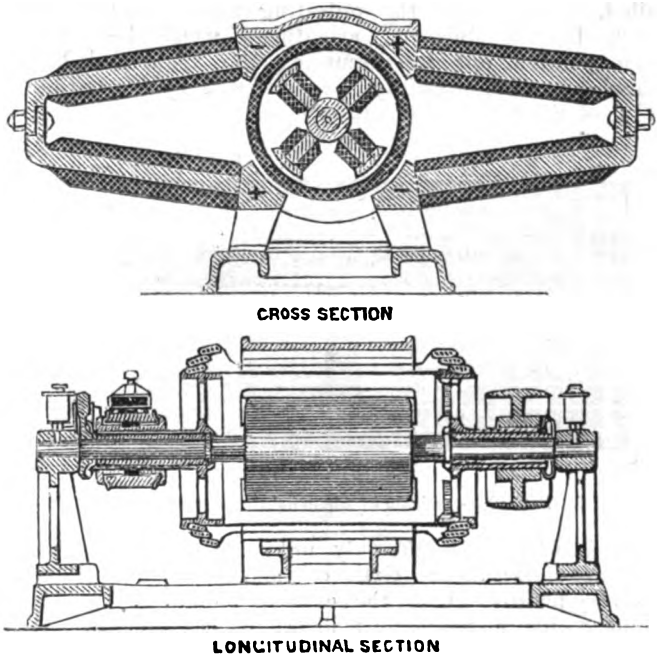

FIG. 2.

We are informed that the present machine, although called an 80-lighter, will feed 110 Swan 20 candle-power lamps at 1,210 revolutions per minute. As will be seen, there are four fields of force, and the armature coils are so arranged as to form segments between adjacent fields. In this machine there are but two collecting brushes, instead of four and six, as in other machines, and the coils are connected to the commutator by a method recently patented by the inventors. The winding is on the shunt system.

The following figures are the results of tests made by the inventors with this machine, which is known in their makers' list as the B shunt:—

| Amperes. | Volts. | Speed. |
|---|---|---|
| 11·7 | 96·9 | 1,210 |
| 17·5 | 96·1 | 1,210 |
| 58·5 | 96·9 | 1,210 |
| 65·4 | 94 | 1,210 |
| 87· | 84·4 | 1,210 |

The resistance of the armature is ·1815 ohm, that of the inside field-magnets 37·7 ohms, and the outside 36·7 ohms.

In our engravings, Fig. 1 is a cross-section, and Fig. 2 a longitudinal section.

## SUBMARINE MINES.

(CONTINUED FROM PAGE 91.)

To determine the power of the Ladd machine in electrical units, resort was had in March 1876, to the method of testing with tangent galvanometer and condenser combined, which has been fully described when discussing the Gramme machine (*vide* p. 561, Vol. XI.). The following results were obtained by this plan:—

OBSERVATIONS WITH THE LADD MACHINE.

| No. of experiment. | Measured values of — | | | | Computed E. | | |
|---|---|---|---|---|---|---|---|
| | T. | R″ | E′ | C | C(R′+R″) | $\frac{E'(R'+R'')}{R''}$ | E′ |
| | | ohms | volts | webers | volts | volts | volts |
| 1 | 1,023 | ∞ | + 7·4 | ·00 | — | — | + 7·4 |
| 2 | 1,023 | ∞ | + 4·3 | ·00 | — | — | + 4·3 |

| 23 | 1,116 | ·17 | + 1·4 | 2·62 | ·81 | + 2·8 | — |
| 24 | 1,023 | ·17 | + 1·4 | 2·62 | ·81 | + 2·8 | — |
| 25 | 930 | ·17 | ·0 | 2·67 | ·83 | ·0 | — |
| 26 | 930 | ·17 | — ·5 | 2·67 | ·83 | — 1·0 | — |
| 27 | 930 | ·17 | — ·9 | 2·72 | ·84 | — 1·8 | — |

Remarks.—The internal resistance (R′) is ·14 ohm.

The last three columns in this table merit special attention. The first is derived from the uniform deflection of the needle of a tangent galvanometer around the coils of which the current was flowing. This needle was so heavy that it failed to respond to instantaneous changes in the strength of the current, and thus measured the *average* current, and hence, indirectly, the *average* electromotive force developed. The last two columns are derived from the discharge of a condenser, and thus represent the subtile variations in electromotive force caused by the fact that the current is not uniform, but simply a succession of waves following each other in the same direction. That the numbers are con-

Digitized by Google

stantly varying, and not infrequently negative, suggests an explanation for what is well known in practice, viz., that apparatus which requires a commutator is not so well suited for the deposition of metals as the Gramme class.

Another important principle connected with dynamo-electric apparatus is illustrated by this table. The current generating the magnetic field of force is distinct from that available for external work, but still the electromotive force of the latter is plainly an increasing function of the external resistance. This should be so, because when a strong current is flowing through the working armature it reacts powerfully by induction, and thus reduces the intensity of the magnetic field, and hence is itself reduced; with a large external resistance, and hence a feeble current through the working armature, the reaction is less. The following table, abstracted from the last, places this matter in a clear light, and proves that for use with a small external resistance the field of force armature in the Ladd machine might advantageously be made larger and stronger.

ANALYSIS OF LAST TABLE.

| Number of Observations. | External Resistance. | Electromotive force. | |
|---|---|---|---|
| | | By Gaugain. | By Condenser. |
| | ohms. | volts. | volts. |
| 5 | ·17 | ·82 | ·53 |
| 10 | ·77 | 2·71 | 3·38 |
| 2 | 1·47 | 3·78 | 2·55 |
| 10 | ∞ | — | 5·47 |

Remarks.—Too few observations with condenser.

It remains to consider what value of E should be adopted in an equation to represent the fuse-igniting power of this machine. The external resistance in fuse firing is usually large enough to ensure a strong field of force, and hence a a relatively high value of E, the numerical measure of which it was thought could best be fixed by direct experiment. At about 1,000 revolutions of the armature per minute, the service fuse exploded through 14 ohms unplugged in the circuit, and failed through 15 ohms. Hence

$$E = \cdot 5\ (\cdot 14 + 14 \cdot 8) = 7 \cdot 5 \text{ volts.}$$

This value is perfectly consistent with the foregoing tables, and has been adopted, giving for the fuse-firing formula, with 1,000 revolutions per minute

$$C = \frac{7 \cdot 5}{\cdot 14 + R''}.$$

This equation indicates that the machine will fire with certainty five service low-tension fuses, coupled in series or short circuit, which is confirmed by experiment. A single fuse can be fired through a resistance of about 14 ohms.

*The Siemens Current Machine.*—This instrument is designed to fire single low-tension fuses without a discharging key. It is exceedingly neat and portable, weighing only 32lb. The case is 9in. by 7in. by 12in. high. The apparatus consists of a soft iron magnet, wrapped with 1·95 ohm of copper wire of No. 17 B.W.G. The poles nearly envelop a Siemens armature wrapped with ·49 ohm of the same gauge of copper wire. The crank is so geared to the armature as to give 10·8 revolutions for every turn, enabling a speed of 1,500 revolutions per minute to be readily obtained.

The electrical connections (Fig. 9) constitute the peculiar feature of the machine. Each terminal binding post is united directly with one end of the magnet wrapping, and with one of the commutator springs; the external circuit thus constitutes a shunt to the magnet circuit. From the general theory of derived circuits, the effective current in the exterior circuit (C″) may be expressed by the following formula, when the armature is revolving steadily and with sufficient speed to produce magnetic saturation in the magnet cores. The resistance in ohms in the magnet circuit is represented by $m$:—

$$C'' = \frac{E}{R' + \frac{m R''}{m + R''}} \times \frac{m}{m + R''}.$$

This peculiar arrangement of the magnetising and of the working circuits rendered the machine an interesting subject of study; and in March, 1876, its power was tested with considerable care. The combined galvanometer and condenser method used with the Gramme gave the following results. The formulæ by which the values of E and C″ were computed are discussed in the next page. See also Fig. 10.

The efficacy of this machine must evidently depend upon a skilful application of the laws of derived circuits, since the strength of the magnetic field of force is governed by the

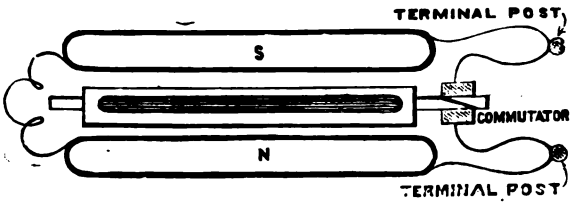

FIG. 9.—Siemens' Current Machine.

amount of current which is drawn naturally through the coils; and hence, in winding the magnets, the resistance of the latter should be regulated by the probable resistance to be used in the fuse circuit.

The conditions to be fulfilled are plainly indicated by the general formula given above. The only unknown quantity in its second number is E. This must evidently be an increasing function of R″, since, if that quantity be zero, no current will circulate through the magnet coils, and E must be zero. The measurements were planned to reveal the law of increase. The direct determination of the condenser failed, by reason of the pulsating nature of the current given by the Siemens armature — which has already been pointed out in discussing the Ladd and Farmer machines. This difficulty was obviated by computing the value of E for each observation by the general formula above

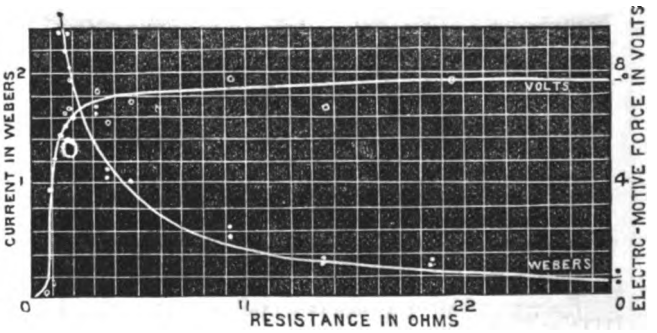

FIG. 10.—Diagram of Siemens' Current Machine.

given, in which it is the only unknown quantity. The results are shown in the sixth column, and they exhibit the law very plainly. Until the exterior circuit is increased to about ·8 ohm, no magnetic field of force is produced. Above this amount, E increases at first very rapidly, and then more slowly until the exterior circuit becomes about equal to the resistance of the magnet coils (1·95 ohm), when it becomes sensibly constant and equal to about 6·8 volts.

Hence the working equation may be found by assuming E to be 6·8 volts, substituting the known values of the other constants in the general formula, and reducing. Ignoring decimals, this method gives the following equation for this individual machine:—

$$C'' = \frac{10 + 5 R''}{R''^2 + 2 R'' + 1} = \frac{5 (R'' + 2)}{(R'' + 1)^2}.$$

The values of C″ in the seventh column of the foregoing table are computed by this formula, and their remarkable

Digitized by Google

agreement with the corresponding measurements, shown by the fifth and eighth columns, establishes the fact that the machine works strictly in accordance with its mathematical theory. The largest available current at a speed of 1,500 revolutions of the armature is about 2·6 webers, showing

(since the two circuits are equal in resistance) that the magnet requires a little current to develop the full power of the machine, which then generates about 5 webers. A service of platinum fuse can be exploded through about 13 ohms. If it be desired to fire several fuses simultaneously with this apparatus, an exterior circuit of about 1·5 ohm, so arranged as to be readily broken to shunt the current through the group, should be provided. From the foregoing data, and general electrical principles, it would be easy to compute the dimensions of a machine of this pattern to supply any desired current.

(TO BE CONTINUED.)

## TELEGRAPH ENTERPRISE AND DEEP SEA RESEARCH.

A correspondent of *The Times* contributed the following article to the issue of that paper for the 7th inst.:—

In *The Times* of the 20th of September, under the above heading, a notice was given of the work undertaken by the ships "Dacia" and "International," belonging to the India Rubber, Gutta Percha, and Telegraph Works Company. These ships had on board the cable for establishing telegraphic communication between the Canary Islands and Spain, and their first duty was to survey the route between Cadiz, the chosen point of departure, and those islands. The general programme of the work was, after landing the shore end of the cable at Cadiz, that the "International" should sail directly for Teneriffe, along a zigzag course, oscillating to a distance of about ten miles on each side of the direct line connecting the two places. One hundred and twenty soundings were to be made during the passage. While she was engaged in this work, the "Dacia" was to follow a similar zigzag course, only with fewer and much larger oscillations. On both ships all observations not interfering with their primary work were to be carried out. Owing to the goodwill animating all, both those in charge and those working under them, a very large amount of useful knowledge has been gained, and the sea surveyed, from being represented on the chart by a mere blank of white paper, now contains more soundings than any other piece of deep water on the globe. On board the "Dacia" 342 soundings were taken, representing an aggregate of 234,766 fathoms of wire and an average depth of 687 fathoms. Besides these, thirty-one soundings were taken to ascertain the temperature and to collect the water at different depths. The amount of wire paid out in these soundings was 25,676 fathoms. During the same time the "International" made 210 soundings, representing 246,376 fathoms of wire and an average depth of 1,173 fathoms. Thus, altogether, in the survey of the bed for a cable 700 miles long, over half a million of fathoms of soundings have been made, and the uneven character of the ground thus revealed shows that the pains bestowed on its exploration have not been excessive. With the very detailed chart of the sea-bottom thus prepared, we see at a glance the serious and numerous obstacles which occur everywhere over the route to the laying of a cable and to its preservation when laid. This will be readily appreciated when it is stated that almost on the direct line connecting the two places an extensive bank was found, covered by only fifty fathoms of water, and rising with precipitous sides from the general level of the ocean-bed to a height equal to that of the peak of Teneriffe above the sea surface. It is not necessary to be an expert in submarine telegraphy to see that this is not the ground over which it would be wise to carry a cable, and that it is true economy to spend a day or two in finding a route to avoid it.

Besides the soundings, observations of the temperature of the deep sea and of the density of its waters, and also, though to a more limited extent, of its fauna, were made as opportunity served. It would be impossible, within the limits of a communication such as this, to give even a summary of the mass of facts thus collected, but a short description of some of the work done on board one of the ships may be of interest to those of your readers who care for this very fascinating branch of research.

The "Dacia" left Cadiz on the afternoon of the 4th of October. The entrance to the Straits of Gibraltar was reached the next morning, and two days were spent in

Digitized by Google

thoroughly sounding its shallowest part, which lies nearly on a straight line connecting Cape Spartel on the African with Cape Trafalgar on the European coast. On existing published charts the bottom is seen to be very uneven. From Cape Trafalgar south, for more than half the distance across, the water does not exceed 100 fathoms in depth, then it deepens to 150 fathoms, suddenly shoals to 45 fathoms, then deepens again, and remains deep till close to the African shore. In order to assist in fixing the positions of the soundings, a buoy was anchored on the mid-channel bank. It remained down for two days, and seemed to excite the curiosity of the ships which crowd the Straits, more especially of a French troopship passing westward, which altered course, first to read the address on the buoy, and then to take a nearer look at the "Dacia." When it was brought on board again the thick wire mooring-rope was found nearly chafed through by the violent currents rubbing it on the hard coral bottom. During the two days spent on this ground, a large number of soundings were taken, the result of which was to define and enlarge the mid-channel shoal from a patch a mile and a half long and half a mile broad to a bank seven miles long from east to west by two miles broad from north to south; further to show that the deep water runs between this bank and the African shore, and that the greatest depth on this, the shallowest ridge, is not less than 200 nor more than 210 fathoms. Considerable interest attaches to a knowledge of this depth. It has been supposed that on it depends the temperature of the deep water of the Mediterranean, as on it would depend the temperature of the coldest water which could find entrance into it from the Atlantic. In the Atlantic, however, outside the Straits, the temperature of the water at 200 fathoms below the surface is decidedly lower than that of the deep water of the Mediterranean. Moreover, it was proved by the observations of Sir George Nares and Dr. Carpenter, in Her Majesty's ship "Shearwater," that, though the currents in the Straits are affected by the tides, there is, on the whole, an inflow of Atlantic water at the surface and an outflow of dense Mediterranean water at the bottom. It was also shown by M. Aimé, in 1848, that the temperature of the deep water of this part of the Mediterranean agrees with the mean temperature of the coldest half of the year at its surface. It is probable, therefore, that the deep overflow of the Mediterranean has more effect in raising the temperature and density of the deep water of the Atlantic than the Atlantic has in reducing that of the Mrditerranean. The observations made on board the "Dacia" quite bear out this view. From the Straits of Gibraltar a westerly course was steered for about 150 miles, then a south-easterly one until the African coast was sighted, when the course was again altered to a westerly one. It was the intention to have taken soundings and other observations along this line for a distance of 180 miles. On continuing the line representing the course on the chart, it was found to cut the line of soundings taken by the steamship "Seine" between Lisbon and Madeira close to a point where the bottom seemed to rise from a depth of 2,400 fathoms to 1,800 fathoms. Before the discovery of the "Seine bank," with under 100 fathoms of water on it, there was no indication of its existence except a similar shoaling from 2,200 to 1,700 fathoms. It was thought, therefore, that another similar bank might exist, and the ship was kept on the same course with the view of going as far as the "Seine's" 1,800 fathoms sounding. At the point where it had been intended to turn a depth of 2,400 fathoms was found; at the next sounding, 50 miles further west, bottom was struck in 485 fathoms. This depth was found at four a.m. on the 12th of October, and the sounding was immediately repeated, with substantially the same result. The whole day was then devoted to the exploration of the bank thus revealed.

The shoalest water found on it was 435 fathoms, in lat. 34° 57′ N., long. 11° 57′ W., and the depth ranged up to 600 fathoms. The shallow water extends for a distance of six miles in an east and west direction, and about $3\frac{1}{2}$ miles in one from north to south. All round the edge it seemed to fall away precipitously from 550 to about 850 fathoms, when the slope became gentle, and the bottom changed from hard coral to soft ooze. In one sounding on this ledge the sinker distinctly struck bottom in 550 fathoms, tumbled over and continued to sink, struck in 620 fathoms, again tumbled over, and finally found a resting place in 835 fathoms. When it came up it had a large brownish-black streak where it had evidently struck obliquely on manganese rock. This was a very remarkable sounding, and quite undoubted. All the conditions were the most favourable—no wind, the sea calm, and the ship motionless. A grapnel with extemporised dredge and hempen swabs was put over in 530 fathoms, and on being brought up the dredge was found much torn, and on the swabs a large quantity of beautiful white coral and many fragments of a crinoid. The coral seemed to belong to two species, and was living and thriving on the remains of dead and decaying branches. The dead branches were in many instances beginning to get coloured brown from deposited manganese. One of the earliest and most interesting of the "Challenger's" dredgings was in 1,500 fathoms, about 200 miles south-west of Teneriffe. The dredge came up full of beautifully branching jet black coral attached to a soft black rock. Thickly clustered among the branches were large silicious sponges, like masses of spun glass. Both the rock and the enamel-like coating of the coral consisted of black oxide of manganese. The same has been found on the ridge connecting Teneriffe and Grand Canary at a depth of 1,000 fathoms, and after severe storms it is sometimes washed ashore on the islands.

Much interest attaches to this bank when looked at as an embryo coral island. The ground rises with a comparatively gentle slope from over 2,000 fathoms to about 800, and is covered with soft ooze. From 800 it appears to rise almost precipitously to 550 fathoms, where nothing but coral is found. It is probable that from 800 fathoms upwards the whole of the substance of the bank is made up of dead coral, supporting a luxuriant growth on its upper surface. There can be little doubt that the height of the bank is increasing, and consequently the depth of water over it is diminishing, year by year. Whether the coral now living on it will continue to thrive as it approaches the surface or not is uncertain; but whether it eventually becomes an island or stops short as a shoal, the character of its development must be that of existing coral islands, and bears out in many important particulars the very ingenious theory recently published by Mr. Murray, the Director of the "Challenger" Commission. An essential condition of the existence of coral, whether in the deep sea or in the shallow water of the atolls of tropical seas, seems to be circulation of the water. This serves the double purpose of bringing food and removing sediment. In shallow water this circulation is produced by the breaking of ordinary storm waves on the shore or on shoals; in deep water it is produced by the transformation of the tidal wave into a current on meeting with obstructions such as ridges or banks, even though they may have a thousand or more fathoms of water on them. In both cases the current is produced in the same way—namely, by the annihilation of a wave.

After exploring this coral bank, so far as time permitted, the ship was directed towards Mogador, on the Morocco coast. Independently of the high land, which is visible for many miles at sea, the approach to the coast is indicated by a rapid fall in the temperature of the water of the sea surface and a remarkable change in its colour. Outside, the temperature of the surface was very constantly 69deg. Fahrenheit. After sighting the land it fell at first slowly, then rapidly, and when two miles from Mogador it was only 61deg. Fahrenheit. The presence of this body of cold water must have an important effect in moderating the climate of places situated on this somewhat desert coast. In the open sea, and away from shore influences, the ocean water in all moderately warm latitudes has the same deep, transparent, ultramarine colour. In colder latitudes this becomes greenish blue and green, and the water loses its transparency. The colour of the water off the Morocco coast is particularly remarkable, for it becomes of a deep and, at the same time, very transparent olive-green colour, unusual in any but icy latitudes. Closer in shore it loses its transparency. On several occasions, and in widely distant localities, I have had the opportunity of gauging the transparency of sea water. In mid-Pacific, with the aid of a

Digitized by Google

water-glass, a metal plate painted white, and having a surface four inches square, could be distinctly seen at a depth of 25 fathoms. On this cruise, in similar "blue water," a larger white object disappeared at 20 fathoms, having been visible at 19, but without the help of a water-glass. On the west coast of Scotland, among the outlying islands, and especially round the island of Eigg, the water has a greenish tinge, and is of exceptional transparency, yet a white dinner plate becomes invisible at from seven to eight fathoms. The light blue waters of the Lake of Geneva have been found by Professor Forel to be comparatively opaque in summer when fed by the melted snows from the Alps, and in winter, when at their clearest, they are not transparent beyond three or four fathoms.

From Mogador a course was shaped for the Seine bank above referred to. It is indicated on the chart by two soundings of 100 and 118 fathoms respectively, at a distance of 12 miles apart. The bank was struck on the position of the 118 fathom sounding, and a day was devoted to its exploration. A couple of "balloon buoys" were anchored in the noon position, namely, lat. 33° 47′ N., long. 14° 1′ W., the depth being 89 fathoms. Hempen swabs were attached to the end of the anchoring line. These balloon buoys are made of india rubber and canvas, and when not in use occupy very little space. They are used for floating the shore end of a cable from the ship to the land, and they are then inflated with air by means of a small pump. They are much like footballs three feet in diameter. The bank was crossed and recrossed in different directions, and found to occupy less surface than was expected. Its length in an approximately north and south direction is six miles, and its breadth from east to west three miles. The depth of water over an area of about 15 square miles varies only from 86 to 100 fathoms. When the sounding work was done the buoys, with their moorings, were got on board, and the swabs, which had been brought up without much dragging, were found to contain a rich harvest of large crinoids of a delicate, reddish colour, and without stalks. These beautiful animals, perhaps the most graceful inhabitants of the ocean, are objects of considerable rarity in zoological collections. Only on one occasion did the "Challenger" make a similar haul, namely, to the eastward of the Philippine Islands, when the trawl came up with a large number of green crinoids, with stalks. It is somewhat remarkable that the reddish crinoids from the Seine bank were accompanied by fragments of dead coral and shells, all of much the same chrome-green colour as the "Challenger's" crinoids from the Pacific. Even where they do abound, it is impossible in the ordinary way of dredging to bring them up without breaking them to pieces. The method adopted on the Seine bank after experience on the coral patch seems to be the one best suited for the purpose. Ordinary swabs are sunk to the bottom and allowed to lie there, great care being taken not to drag them. If left sufficiently long, the animals crawl over them and attach themselves securely to the tangled yarns, when they can be removed to the surface without damage.

From the Seine bank a southerly course was steered for 170 miles, where a sounding on the evening of the 19th of October gave 1,189 fathoms where a depth of at least 1,800 fathoms was anticipated. Another bank was immediately suspected. Three miles further, on the same course, 1,386 fathoms were found. If a bank existed it had, therefore, been passed over. The course was immediately reversed, and after steaming seven miles back a sounding gave 810 fathoms; three miles further back 414 fathoms were found, and two miles further 66 fathoms. One mile beyond this sounding 230 fathoms were found. The ship was again turned round and steered to the southward for about a mile and a half, when a buoy with lights was put over in 175 fathoms, and, as it was already past midnight, the ship lay by it till daylight. As this bank lay very close to the proposed line of cable, two days were devoted to its exploration. It was found to be of an irregularly triangular shape, broader towards the north and tapering towards the south. Its greatest length from north to south and breadth from east to west were found to be equal, and eight and a half miles respectively, while the total area, with less than 100 fathoms of water on it, was 50 square miles. A boat was anchored in the noon position of the 21st of October—namely, lat. 31° 9′ 30″ N., long. 13° 34′ 30″—in 58 fathoms of water. This is near the centre of the bank, and a little to the southward of the shoalest sounding, 49 fathoms. Swabs had been attached to the mooring rope of the buoy; they had also been attached to the moorings of a couple of balloon buoys in rather shallower water, but during the two days that they were down the ropes got so chafed that they broke when being recovered. Hopes of a rich collection had been high, consequently the disappointment was great. Swabs had been attached to the boat's cable, and they were recovered, but as they had only been a very short time on the bottom, little was expected and little was found on them. A few broken and decayed shells made up the harvest.

Advantage was taken of the buoy being anchored in mid-ocean to make some current observations. It is an almost universal experience of ships making a passage from the north to the Canary Islands to be set very considerably to the eastward of their course, and many disastrous shipwrecks have been the consequence. It appears from recently-collected observations that the general set of the current is about east-south-east, and its velocity averages 16 miles per day. Only a few weeks ago a buoy belonging to the United States Lighthouse Department was washed ashore on the north coast of Teneriffe. Knowing how the tidal wave is transformed into a current on approaching the coast, it seemed not unlikely that the occurrence of so extensive a shoal as the "Dacia bank," as it has been called according to recognised precedent, might produce the same effect. Accordingly, before the buoy was brought on board again, I spent some hours in a boat riding to it and determined the direction and rate of the surface current at frequent intervals, while the ship went on with the sounding at a distance. The result of these observations was, shortly, to show that, as in the case of Gibraltar current, the south-easterly current in this part of the ocean is affected, and at times reversed by a tidal current. Down to a depth of 70 fathoms the current was found to be setting in nearly the same direction as at the surface, but with somewhat greater strength. The "current drag" used on this occasion was a "tow-net" made of fine but stout muslin, about three feet long and one foot diameter at the mouth, tapering to a cone in the bag. The mouth was kept open by a stout iron ring, which was made fast to the sounding line which passed diametrically across it. The water was of so clear and transparent a blue that it could be distinctly seen down to a depth of 19 fathoms; and with a weight of 14lb. at the end of the line, it set itself perfectly steady and almost rigidly in its direction. It was allowed to remain nearly an hour at a depth of 35 fathoms, and about the same time at 70 fathoms; and from both depths it brought up large collections of animals. The phosphorescence of the water in these parts of the ocean is a familiar and almost nightly appearance. It is produced by a minute animalcule, which comes to the surface as it grows dark, and disappears again with returning daylight. It was a remarkable, though not unexpected, fact, that the tow-net which had been at 35 fathoms, though it brought up plenty of animals, brought none that were phosphorescent, while after being at 70 fathoms it came up teeming with them, and even in daylight the muslin looked as if it had been dusted with fireflies. On leaving the Dacia bank a course was shaped for the Salvage Islands. Unfortunately, the weather, which had hitherto been very fine, changed, and it was so stormy that landing could not be effected. A line of soundings was run between the Great Salvage Island and the Piton Islands, about 12 miles distant, and a general depth of about 400 fathoms was found. The two islands are therefore peaks on a bank similar to those described above. They consist, however, of igneous rock. On the evening of the 23rd of October the ship bore up for the Grand Canary, where she dropped anchor the next day. In carrying out her part of the work the "International" added her contribution to the number of submarine banks, but the limits of a communication such as this do not admit of their being further referred to.

Digitized by Google

It results from the very large number of soundings made by these ships in a limited area that soundings taken at considerable distances apart do not necessarily give any idea of the formations of the sea bottom. The soundings of the "Challenger," which were taken in some parts at distances of 100, in others at distances of 200 and more miles, when taken alone necessarily showed the bottom of the sea to be almost flat, or only gently undulating. But even before her voyage terminated, Captain Belknap, U.S.N., in the "Tuscarora," had by the perfect use of wire, run a line of soundings at distances of 30 miles apart, across the North Pacific, and from this line it was apparent that the ground at the bottom of even the deepest ocean is much less than had been anticipated. We may feel reasonably certain that we know the greatest depth of the ocean. It almost certainly does not exceed or even reach 5,000 fathoms. What is now wanted is to discover the shallow parts of the ocean, and for this we require close and careful search. The sea between Cadiz and the Canaries has been subjected to such a search, and with the most satisfactory results. It has been thought that the Madeira, the Canary, and the Cape Verd groups of islands are the remains of a once existing, now submerged, Atlantic continent. When, however, we look at the banks which bear the names of the Seine, the Dacia, the Josephine, and the Gettysburg, we are encouraged not to mourn a lost, but to expect a coming, Atlantis.

## THE SWAN UNITED ELECTRIC LIGHT COMPANY (LIMITED).

The first ordinary general meeting of this Company was held on Tuesday at the Cannon-street Hotel, Mr. James Staats Forbes in the chair.

Mr. JAMES H. IVORY (the secretary) read the notice convening the meeting, and the report of the directors was taken as read.

The CHAIRMAN: I have had the pleasure of meeting the proprietors twice since the formation of the Company, thirteen months ago, and I want to call your attention to the fact that these accounts represent the transactions for thirteen months, the time which has elapsed since the initiation of the Company and the 30th June. We had our statutory meeting, at which meeting we rather anticipated what might, perhaps, very soon arise, the amalgamation of the companies, the Swan and the Edison; then we had very recently a meeting in order to carry out an agreement to effect that object, and at that meeting, in fact at both those meetings, I was enabled to address the proprietors at some length, and to put them as we say abroad at the height of the question on the general position, as well as to indicate some details of the business. This is a very interesting meeting in one sense, because it is the period when for the first time we are called to account, I mean to account in the sense of having to present accounts, and to explain, if called upon, the details of those accounts, and to judge as far as we can from them, with your assistance, the probable outcrop of this new enterprise on which we are all embarked. We have purposely made the report a little full, and you will see what it is. It divides itself almost naturally into three separate heads, and our business means really three separate things—the manufacture of lamps, first. Everybody knows Mr. Swan's patent is a patent more especially having to do with the manufacture of that wonderful implement, the Swan lamp. We are empowered also under our general Articles to become not only manufacturers of lamps and erectors, or supplyers, of what are called installations—which means all the preliminary machinery antecedent to the use of the lamps at the end of it—but there is also another branch, or rather, should say, another thing which we may do under our Articles—he erection and carrying on of works for the general lighting of large districts. These are three distinct heads, and what I want to say, as a sort of preliminary note, is that you must not assume that the results of the thirteen months' work, as evidenced in these accounts, has anything to do with but a very small portion of the Company's business. We have, of course, been able to develop most of all the manufacture of lamps. When I say "most of all," that is only a very limited development compared with what there is a reasonable probability of its assuming year after year in years to come. Immediately, I have no doubt, there will be a very large development, but that, of course, depends somewhat on the development of the other things—the erection of detached installations, which means that a number of factories, theatres, detached buildings or establishments—and there are thousands of them in Great Britain—are sufficiently great consumers of light to justify the erection for themselves and their own purposes of this installation machinery—these engines and dynamos and leads of which one hears and reads. Well, that, of course, is a matter which must go slowly. The very thing is so novel, and the competition of gas, of course, is carried on under such great advantages. People know what they have got in the gas light, and however eager they may be to avail themselves of something better, a great many people prefer to follow rather than to lead in these matters. They are waiting to see; there is a good deal of waiting to see going on. That is much more common with the third head, the general lighting of large districts, and, of course, it was quite impossible to do anything with that until the companies prepared to undertake it had ascertained what their legal position was. With a private property there is nothing to prevent your doing what you like; you can move any number of engines or dynamos, or make any number of leads, without being interfered with, but the moment you get into general lighting, that means interference with public rights, and everybody knows you cannot do that without the authority of Parliament or some competent tribunal. Well, the greater part of our time during the last twelve months has been occupied first of all in considering this general public lighting question, and in taking measures necessary to watch what the Board of Trade, the authority which has been primarily entrusted with the consideration of this question, and after that Parliament, would expect us to do, and the amount of limitations they would impose upon us. Well, all that has been done. Thirteen months is not a very long time when you look back upon it for the working out of a matter of this sort. Our position is very different from what it was a short thirteen months ago, when we took over from the old company the factories and things at Newcastle, and there was a good deal there to be done. Well, what needed doing we have done; we have extended them and made them capable of producing more work, and we believe better work. With respect to installations, we have done something in that direction and especially with steamships. Steamships appear to be a very fruitful source of consumption of this electrical light machinery. In the course of time we have been enabled to do a certain amount of installations for the different steam shipping companies. It is a business which is not only being perfected by experience, but we have no doubt it will grow, and grow very rapidly. Then with respect to public lighting, we have got our provisional orders. Of course London is a very big place, and the Swan Company are a very small company, and when you know, or rather when the philosophers and people who study this matter tell us, the lighting of every square mile of London means very large sums of capital, you will see what a gigantic job it would be to contemplate the whole thing. Besides, it would not be very prudent to go too fast. We should not be in a hurry to do more than we see our way to do. This thing is quite crude, quite in its infancy; there is a great deal to be done to it to make an absolutely certain and efficient machine and a paying machine, and we have been most anxious to go prudently rather than too rapidly, because these undertakings under Acts of Parliament do involve serious and many responsibilities, and we have not thought it desirable in your interest to entertain them without a great deal of caution. However, now we have done it; therefore at this moment our business consists of manufacturing lamps, which lamps themselves are from time to time improved. Experience reveals certain improvements as being necessary, and happily we are in possession of the machinery, and, what is more, of the means to meet those necessities as they arise. You will see it is mentioned in the report that the pattern of the original lamp is not well adapted for some of the purposes we are now called upon to serve, and the attention of Mr. Swan and Mr. Sterne, two of the most competent people I suppose living for that object, has been engaged upon that, and we are day by day improving the lamp, or I might say, adapting it to the new uses which from day to day are revealed. Well, perhaps I had better go through this report paragraph by paragraph. You will see the first paragraph says:—"During the thirteen months the sale of lamps has steadily increased, 180,000 have been sold, and the profit arising from these sales amounts to over £7,000." There has been rather a considerable profit upon them, and if our business had been simply that of lamp makers, our capital simply involved in that, that would have been a very good business transaction. I have no doubt whatever that, assuming (one has to assume a good many things in life) these patents to be maintained, as we believe they will be, and assuming the consumption of these lamps to grow very rapidly, as we believe it will, then we have got two factors quite ascertained, namely, that the lamp can be produced at a price which, consistent with a very low charge to the public, will leave us a fair—I may say a usual- trade profit on its transactions. Therefore, so far as the capital of the Company is invested in lamp making, I look upon that—and my colleagues I am sure agree with me—as beyond question a first-rate investment. Our position, of course, is not in the least damaged—on the contrary, it is very much strengthened—by the fact that, whatever merits the Edison patents have, we now possess them. And whereas it was debateable (might have been at all events debateable) as to whether Mr. Edison did not more or less infringe Mr. Swan's patents, or as to whether Mr. Swan did not more or less infringe Mr. Edison's patents, what appears, as far as we are advised, to be perfectly certain is that Mr. Swan and Mr. Edison together are invulnerable, and will be a terror to evildoers in the shape of infringers. Well, we shall have to deal with the infringers later on; we must first of all set our house in order, and then if we find these wonderful inventions—because they are wonderful—being infringed, we shall have to do our best to vindicate our claim to have the benefit of them, at all events for that limited time which the patents have. Well now we come to the next thing, detached installations. That is a much more complicated question, and it involves considerations of a financial kind, and you will easily understand them when I tell you that an installation means first of all the manufacture of an engine to drive a machine. Well, there are plenty of people who make engines to drive machines, but these engines require certain peculiarities. I have no doubt in time we shall find plenty of people who make them for tender at very moderate profits, and therefore it is a consideration whether these companies, and companies like the Edison and Swan United Company, need involve themseves in a financial responsibility of starting a factory to make engines where the dynamo stands upon rather a different footing. But after all it is only a machine, and though it is a machine somewhat more novel than making an engine to generate power, there are a great many heads engaged upon it. As you know there are a number of patents about the dynamo—Mr. Edison's and some others—the Gramme machine, all kinds of patents, everybody, of course, declaring that he has the particular thing. But we are in the happy position of having many people working out at their own cost and risk the problem as to which is the best thing for us to use when we choose to use it. It may be that we shall not have to be manufacturers of dynamos, but we are hardly, I think, in a position yet to decide that; but, of course, what we do want to avoid is putting our hands into our pockets and spending large sums to establish manufactories if we can get other people willing to find the capital, and give their brains, and produce a thing we want at a very moderate trade profit. I think myself it may come out in that way. That applies even more fully to the street lighting—what is called public lighting. That is a thing behind the other parts of the business, and certainly much more complicated than anything else we have to deal with. I think it is not improbable we shall find a great number of people willing to put

Digitized by Google

their capital in to work out these difficult problems in different parts of London, and if we are sure—as I think we are pretty sure—of the lamp, well then we shall enjoy the benefit of all their capital and of their work, because the lamp is the flood gate. All your power s of little use unless at the of end it you have the best lamp possible. Well, if we have the best lamp possible, and behind it we have the patent, it is obvious their labour is in vain who go into these public installations unless they are licensees of this Company. Well, now, those are the elements out of which we have got to make a business. It does not very much affect the proceedings of the last thirteen months, more than this, that it may be satisfactory to you to know that in conducting this Swan business we have learned a great deal. I am sure that every one of us has. I dare say I may venture to say Mr. Swan has. Mr. Stern and others are a good deal wiser to-day than they were thirteen months ago. We have had to go through a great many trials, and to consider a great many things, and I think we have now a pretty clear forecast of what it will be wise to do in the interests of these two companies which now happily are united. I think all the rest of the report speaks for itself. You will see we have made a certain amount of profit on the erection of these separate installations. Some of them are cases in which we provided the fittings, and rigged up the whole thing at the cost—of what shall I call him?—the customer, taking a fair trade profit on the undertaking and being done with it the moment we were done with it. Then with regard to the Law Courts, they were fitted up at the cost of the Government, and they paid us for the work done. We made a reasonable profit on it, and we handed over the whole thing to them, and they have all the responsibility of the future, and the daily maintenance. So far as we are concerned it is settled. Some we are doing on the supply system. I think the other plan is better. "A bird in hand is worth two in the bush." When we do work and get paid as we go along, whatever the profit, you get t in your pocket. When you contract to supply a light you have all the responsibility and anxiety and risk of solving the question as to whether the price at which you agree to supply covers the primitive outlay, the depreciation of the material, and the cost of producing the light. Well, some of our installations have proved that to us they have not paid, and I am not surprised that they have not paid, because they were avowedly experimental. They were all put up for the purpose of establishing the practicability of producing a light which was a usable light and not with the view of making a profit on any particular transaction. Fortunately they are all what are called short time contracts, and can be put an end to. The question in our minds is whether it is worth while to go on in those particular cases, and make use of these installations for the sake of advertisements, or whether it would be worth our while to put out the light in those cases. That is a matter we shall have to treat with some judgment; in fact, the old world wisdom is especially applicable. We must not hide our light under a bushel. It is just the same thing as when one pays a good deal for advertisements in the newspapers, trusting the thing will result in a mackerel being caught for the sprat thrown out. You will see we have some provisional orders. We were in the happy position of being able to pick and choose out of all London. We picked and chose some points which seemed to us to be most desirable centres as affording within the area limited by these orders the earliest probable opportunity of doing business on a large scale. They are adverted to in the report. There is another at the Victoria Station. Well, I am looking forward to that experiment myself with a great deal of interest, because I dare say everybody knows that apart from my position in the Swan Company I have some interest in the Victoria Station. I confess it seemed to me that it was very desirable to establish one or two things, such as whether an incandescent lamp—because that is our business—would light up complicated buildings such as a great London railway station. By that I mean not merely that part of it which the public see, the platforms and booking offices, but the large number of auxiliary buildings, offices of all kinds, and establishments which the public do not see. Well, Mr. Crompton and Mr. Swan believe that the incandescent lamp will do it. If it does there will be a constant advertisement of the greatest value, and it will settle one question, because incandescent lighting on that scale has not been tried in any similar place in London. It will solve one or two other things which it is very important to us should be solved, we shall know what we are spending to produce a result; we shall know what we are to receive for that result, and we shall be able by a little care and analysis to see how far the one fits the other. Well, that is most vital, because all these electric lighting companies are tumbling head over heels, as you must do when you have to assume a great many things. These assumptions happily sometimes end in a profit, but more frequently they end in a loss. What we want is absolute accuracy to guide us. If the Victoria Station should turn out to be a good thing, as some of the technical people believe, well and good; if it turns out a less good thing we shall have the means of making it a test case, and if it reveals any weak places we shall be very careful to stop them up in future. That is the most advanced of all these proposed installations, and has become the kernel, so to speak, of public lighting, because at Victoria Station the works are being laid down with reference not merely to the contract of lighting that station, but to an extension of the lighting power to the adjoining stations and places, of which you know there are a great many. There is the Brighton Railway, the Grosvenor Hotel, the Underground Railway Station, under the street opposite, which we can get at. The Stores are very anxious to be lit, and there are several big hotels there. In fact, there is a rich, and populous district within that area. Well, that will be an opportunity of testing this public lighting question. The other one is in the Strand; every one knows the Strand. I dare say a good many of the proprietors have been to the Savoy Theatre, where this thing is being carried on in a manner which has given very great satisfaction to the theatre people. There is a charming light and cool atmosphere—it has been quite successful from that point of view—but whether it will be so successful from a financial point of view I do not know. It has not been tried on a sufficiently large scale. But there is a large area of lighting. Well, we shall have to feel our way very carefully with that. There is a motto which says, "He who goes slowly goes surely." That will be the motto of this Company. The chances are too great, and the cost involved is too great, to justify our pushing on without a very firm foothold. Well, now I come to the paragraph as to the foreign business. I dare say I need hardly recall the attention of the proprietors to the fact that in fusing with the Edison Company we have only fused the British business, and therefore the Edison and Swan Companies, of which you are members, were only incorporated for the purpose of carrying out business in Great Britain, the Edison patents for Europe having been handed over to another combination. That being so, we, in the bargain, retain our foreign patents, and therefore we are now a sort of duplicate body. In one sense we are the Swan and Edison, but in the other sense we remain the Swan Company; and it will be necessary for a time at least to keep alive the whole machinery of our Company, in order that we may well look after, and turn into money, these foreign patents in respect to which we have paid such large sums of money. As in England, so abroad, Mr. Edison and Mr. Edison's assignees, or assigns rather, think theirs is the only patent, and of course if they can succeed in establishing that position they have a very fine property. We think the same arguments which induced us to defend our patents in Great Britain are good abroad. We are trying to establish the validity of our patents abroad. I suppose the same sort of thing will come about—in fact, we are in the preliminary stage, we are in litigation. Well, we were in litigation in England. When the parties came to close quarters they found both of them that the big words which had been used on either side in the early stages of the quarrel had to be slightly modified. It reminds one of the boys in school, who get up to the squaring period and then diminish their energy. Well, that is the case with us; we are in the fighting attitude, squaring up to each other. But the sound is not so voluminous, and perhaps it may not be uninteresting to you to know that litigation being pending, negotiation has commenced, based on putting our horses together in Europe as we have done in England. Well, if so, the same benefits will follow—we shall be united for the purpose of defending all our patents instead of being divided, trying to prove that neither of us has a patent. You will easily understand the difference in the position; but, meanwhile, we have a separate and distinct property, in addition to our British interests in the new United Company. You will see we have parted with one portion of those patent rights—the Spanish. In respect to that, we got rather into a difficulty. Spain is rather a queer country, and though we got into the hands of tolerably respectable people, there were plenty of opportunities for them to open questions as to agreements which had been entered into; and in order to prevent litigation, or, in fact, to get out of it, we determined we had better take what money we could and hand over the patent rights of Spain to the Company. In conclusion, the Chairman said that the profits would have appeared larger only the whole of the expenses, which naturally had been heavy, had been charged to this year's accounts. He was perfectly certain that the policy of the Board—that of playing a waiting game—was a safe one, and that it would place them in a position of considerable advantage over those people who had been trying to get the start of them. He moved the adoption of the report and accounts.

Major-General J. S. TREVOR seconded the motion.

Some discussion ensued with regard to the expenses, and in reply to questions

The CHAIRMAN stated that they had been obliged to keep up an expensive staff, but the proportion of expenses would not appear to be nearly so heavy when they had more business to do. In fact, he might say that they had now a duplicate staff, and the attention of the Board of the United Company would be directed to weeding out those who were not absolutely necessary for the carrying on of their business. He had said that the whole of the preliminary expenses, and other expenses which might have been spread over a series of years, had been debited to this year. Respecting the probability of a call, it was not the intention of the directors to make a call unless they saw their way clearly to employing the money in a profitable manner. With regard to the prospects of the future, he had the most complete confidence, and he believed his colleagues joined in that confidence.

The motion for the adoption of the report was then put, and carried unanimously.

The retiring directors and auditors were re-elected, and a vote of thanks to the chairman and directors then terminated the proceedings.

## BIRMINGHAM AND WARWICKSHIRE BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

Mr. Hammond presided at an extraordinary general meeting of the above Company held at the Cannon-street Hotel on the 7th inst., and in moving "That it is desirable that this Company should be wound up voluntarily, and that the same be accordingly wound up voluntarily," said they had so recently met, and had then so fully gone into the position of the Company that he did not think it necessary to recapitulate what was said on that occasion. The practical portion of the amalgamation agreement laid before them at the last meeting had been carried out, the assets having been handed over to the Hammond Company, and the latter having under the agreement allotted the shares.—Mr. T. A. Hitchins seconded the motion, and it was carried *nem. con.*—Mr. Hammond then moved that Mr. Philip Latham, of No. 110, Cannon-street, being the person named by the Hammond Company, be and is hereby appointed liquidator of this Company, with full power to take such steps as may still be necessary to carry out the agreement already entered into between this Company and the Hammond Campany dated the 10th November, 1883." The Chairman explained that the only steps which Mr. Latham could now take to carry the agreement into effect were those which had reference to the "odd" shares. He might add that on presenting their certificates to the Hammond Company the shareholders in the old company would find themselves in possession of two shares over the number they originally held in the Birmingham Company. It would, he said, be the business of the liquidator to take the transfer of any odd shares which was necessary under the agreement. This was seconded by Mr. Plumbly, and carried. In conclusion, the Chairman said that under the Articles of Association another meeting would have to be held, of which due notice would be given, to confirm the resolutions then passed. He might say that those who wished to get their Hammond shares could do so at their convenience, as they were now ready for distribution. A vote of thanks was then passed to the chairman, and the meeting separated.

## YORKSHIRE BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

An extraordinary general meeting of this Company was held at the Terminus Hotel, Cannon-street, on the 7th inst., for the purpose of passing the following resolution:—"That it is desirable that this Company should be wound up voluntarily, and that the same be accordingly wound up voluntarily." Mr. H. Lowe presided.

The CHAIRMAN stated that the meeting was purely formal, and had been called in accordance with the provisions of the Companies Acts. The resolution before them was one which the Act of Parliament required them to carry. The whole of the proceedings were fully detailed at the last meeting, and he had nothing whatever to communicate in addition on the present occasion. He concluded by moving the resolution.

Mr. H. W. MAYNARD seconded the motion, which was carried unanimously.

The CHAIRMAN then moved a resolution appointing Mr. Philip A. Latham to be the liquidator, and to take such steps as may still remain necessary to carry out the agreement entered into between the Company and the Hammond Company on the 23rd of October last.

Mr. MAYNARD seconded the motion, which was also carried unanimously. The proceedings then terminated.

## THE EASTERN ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

Report of the directors presented to the second ordinary general meeting of the Company, held at the Terminus Hotel, Cannon-street, London, on the 14th inst. The directors submit the balance-sheet of the Company made up to the 30th September, which, together with the report of the auditors thereon, will, they consider, be fully explanatory of the position of the Company. In the last report allusion was made to the order of the Supreme Government of India prohibiting the use of overhead conductors for electric lighting. Notwithstanding the most strenuous efforts at home and in India to obtain a withdrawal of this order, the Government signified their intention to enforce it, and to this arbitrary official action is to be attributed the chief part, if not the whole, of the subsequent difficulties and disappointments that have attended several of the Company's undertakings in India. Many contracts that could have been secured had to be declined in consequence of the greatly increased outlay required for labour and material for underground cables, and in other cases, where the lighting, having been undertaken, has been continued, the change from overhead to underground conductors has reduced the profits of the Company almost to *nil*, or has even occasioned a loss. In incandescent lighting some valuable time was lost owing to the extensive injuries received in transit by the earlier shipments of the accumulators and the insufficiency of appliances at hand for putting these in repair. With later shipments, and with the aid of specially trained men sent out by the Electrical Power Storage Company, excellent work has been done, and there are a large number of orders for this system of lighting waiting to be taken up. A favourable arrangement has been made with the Swan United Company whereby this Company secures for a period he exclusive agency for the Swan lamp for India and its dependencies.

From an early period it became apparent that the formation of local subcompanies was of great importance to the Company's interests, and during the months from April to August of the present year, the managing-director in Bombay was actively engaged in negotiations with leading European and native gentlemen for the establishment of a Bombay Electric Light Company. These negotiations were continued until the month of October, and the Company was provisionally formed and advertised, and a large part of its capital subscribed, when some of the provisional directors became dissatisfied with the prospects of the undertaking, and the scheme was abandoned. The Company's works in Bombay have been carried on from three centres—Mody Bay, Byculla, and Tardeo. The two first are considered to be valuable properties, and it is believed that the money paid for them, and the buildings erected will prove a good investment. A license from the municipality of Bombay for ten years to open up roads, carry on works, &c., has been acquired by the Company. This license very materially strengthens our position in Bombay. It was only obtained after much consideration, and the granting of a similar license to any other company is improbable. In Egypt there was a prospect of extensive and profitable contracts, but owing to the outbreak of the rebellion the calculations of the directors were entirely upset. Subsequent to the restoration of peace the work of the Company was resumed, and several successful exhibitions were given both of arc and incandescent lighting, but it became clear that confidence and capital were not yet sufficiently restored to support so novel an enterprise; the directors therefore determined to recall the staff and close the works. The extension of the contract for public lighting in Malta, which had been anticipated, and which would have made that establishment at least self-supporting, was withheld by the Government pending further consideration, and the agent of the Company was notified that should the Government decide to increase the number of lights the contract would be open to competition. Under these circumstances the directors gave notice to stop the lighting, which was being carried on at a loss, and to save further expenditure by recalling the electrician in charge and closing the works. At the present time the agent of the Company is endeavouring to form a local company to take over the plant and continue the lighting. In Penang an extensive contract for street lighting has been offered to the Company, but owing to the Indian and Oriental Storage Company not having completed their works for the transmission of power from the waterfall to the town, the directors were not in a position to accept it. The contract is, however, still open. In conclusion, the directors would briefly allude to the causes which have been most prejudicial to the prosperity of the Company. 1. The action of the Indian Government in prohibiting overhead wires. This alone was sufficient to paralyse all efforts at progress, the consequences of the order being exasperating delays, greatly increased difficulties in practical working, and profitless heavy additions to expenditure. 2. The general collapse in prices of shares in electric light undertakings. This could not be without its effect in India, and combined with the order of the Government, and the warning given as to the danger of exposed conductors occasioned alarm and suspicions that will only disappear with time. 3. The non-realisation of the expectations that had been formed as to contracts for works and sales of plant, and a consequent locking up of capital in machinery and plant still unemployed. 4. The imperfect knowledge possessed by the mechanical electricians and engineers that were available in the early period of the Company's work. The extreme difficulty of securing competent men, and the incomplete state of the electric lighting industry generally, caused many unforeseen failures, and introduced an element of great uncertainty in the framing of estimates.

TO be SOLD, by PRIVATE TREATY, the whole PLANT and MACHINERY of an ELECTRICAL MANUFACTURING WORKS, consisting of Lathes, Screw Making, Slotting, Shaping, and Drilling Machines, together with Hydraulic Press, Dynamo Machines, Testing Instruments, including Wheatstone Bridge and Thomson's Galvanometer, Serrin Lamp and Edison Lamps, and a quantity of useful Stores and Tools, to be sold in lots to suit purchasers. For particulars and permission to view, apply to the LIQUIDATORS, Pyramid Electric Company (Limited), Whitecroft, near Lydney, Gloucestershire.

AN ELECTRICAL ENGINEER, with good mechanical knowledge, and three years' experience in construction and design of dynamos (Gramme), as well as in arc and incandescent installations, DESIRES SUITABLE EMPLOYMENT. Address, A. D., Post Office, Atherton, near Manchester.

Digitized by Google

## NOTES.

ELECTRICITY ON THE STAGE.—Following the example of English theatrical managers the ballet dancers at the Paris Opera House wear an incandescent lamp on their forehead.

THE TELEGRAPH IN SIAM.—The erection of the Siamese telegraph line from Bangkok to the Burmese frontier has so far progressed towards completion that a requisition has been sent to the Government of India for the necessary signallers to work it.

LONDON AND PROVINCIAL COMPANY.—Mr. W. L. Grimwade, of 32, Queen Victoria-street, public accountant, has been appointed by Mr. Justice Chitty official liquidator of the London and Provincial Electric Lighting and Power Generating Company.

EARTHQUAKE.—A Reuter's telegram, dated Constantinople, Dec. 15, says:—A strong shock of earthquake has occurred at Konia. A large caravansary fell in, and two persons were buried in the ruins. The governor of the city announces that no other damage was done.

THE ST. GEORGE TELEPHONE COMPANY.—A petition for the winding up of this company was presented to the High Court of Justice, Chancery Division, on the 15th inst., by Messrs. Paterson and Cooper, of 76, Little Britain, E.C., and is directed to be heard before Mr. Justice Chitty on the 12th January.

INSTITUTION OF CIVIL ENGINEERS OF IRELAND.—At the annual meeting of the Institution of Civil Engineers of Ireland, held in Trinity College last week, the Mullins medal was presented to Mr. Angelo Fahie, C.E., M.S.T.E. and E., for his paper on "Magneto and Dynamo Electric Machines," read during the past session.

COUPONS.—The Eastern and South African Telegraph Company notify that the coupons due on 1st January, 1844, on the Five per Cent. Mortgage Debentures will be paid on and after that date at the banking house of Messrs. Barclay, Bevan, and Company, 54, Lombard-street, E.C. Coupons must be left three clear days for examination.

JACK-OF-ALL-TRADES.—We notice in a recent issue of the *London Gazette* that a certain tradesman in Nottingham has become bankrupt. He is described as a "fancy draper, hosier, and electrician." We wonder whether he was a fancy draper before he was an electrician, or an electrician before he was a fancy draper—but perhaps he was only a fancy electrician.

THE INSTITUTION OF CIVIL ENGINEERS.—Mr. W. H. Preece, F.R.S., was elected a member of the council of this institution at the aunual meeting held on Tuesday evening last. Until now no telegraph and electrical engineer has sat on the council of this important body, and Mr. Preece has the honour of being the first to be chosen to represent that branch of engineering.

THE RYSSELBERGHE TELEPHONE SYSTEM.—It is reported that the Belgian Minister of Works has approved a convention with Messrs. Mourlon, of Brussels, for the appropriation of the Belgian telegraph lines in view of the application of the Rysselberghe telephone system. It will be remembered that M. van Rysselberghe claims to be able to send telephone messages over wires which are being used for telegraphic purposes.

THE TELEPHONE IN CEYLON.—The Oriental Telephone Company have opened an exchange at the Law Courts, Colombo, in connection with their central exchange, and another exchange will be established at the Wharf. These exchanges will be what are called "open," that is, free to any one, at a certain sum. Thus, 25 cents will be charged to non-subscribers, and 12½ cents to subscribers speaking to non-subscribers.

COLLIERY LIGHTING.—The Maxim lamps fitted up at Page Bank Colliery about a year ago by Mr. Edward H. Liveing for the Maxim Weston Electric Company have lasted very satisfactorily. A large proportion of them have been running from 1,200 to 1,500 hours, and are still at work. The current is supplied by a Maxim dynamo and a Weston shunt-wound 50-light machine. The lamps were carefully selected before being fitted up.

LIGHTING THE CRYSTAL PALACE.—The directors of the Crystal Palace Company invite tenders for the lighting of the naves and centre transepts by arc lamps only. Estimates are to be furnished for a term of one, two, or three years at the option of the directors, in accordance with the circular containing full information and instructions as to the requirements, which may be obtained on application to Mr. Gordon Cleather, manager.

THE AMALGAMATION OF GAS COMPANIES.—The Commissioners of Sewers have expressed the opinion that the proposed amalgamation of the South Metropolitan Gas Company with the Gas Light and Coke Company would be to the disadvantage of the gas consumers, and that the Board of Trade should be informed that the matter should be dealt with by Parliament, so that the views of the local authorities in the matter might be expressed.

SHOPLIGHTING.—An intelligent lad of seventeen, the son of Mr. E. Storey, ironmonger, of Oundle, has for twelve months past lit up his father's shop and premises, economically and well, with the electric light, and gas, we understand, has not been in use there since. To the credit of young Storey it must be added that he also made the engine which drives the electric lighting machinery.—*Martineau and Smith's Hardware Trade Journal.*

DYNAMOS AND TELEGRAPHY IN GERMANY.—Experiments are being made at the German Central Telegraph Office in Berlin with currents supplied by dynamos for telegraphic purposes instead of battery currents. The experiments up to the present have been confined to aerial lines from Berlin to Magdeburg, Frankfurt-on-Main, Cöln (Rheim), Königsberg (Prussia), and Riga, both Hughes and Morse instruments having been used with a most satisfactory result.

ROYAL INSTITUTION.—From the programme for the Friday evening meetings of this institution we find that Professor D. E. Hughes, F.R.S., will read a paper on the 29th of February on a "Theory of Magnetism, illustrated by experiments." Professor Tyndall, F.R.S., is announced to give a course of six lectures at the institution on "The Older Electricity, its Phenomena and Investigations." The dates of the lectures are February 28, March 6, 13, 20, and 27, and April 3.

EASTERN TELEGRAPH COMPANY.—The Eastern Telegraph Company announce the payment, on January 15th next, of a dividend of 3s. per share on the preference shares, less income-tax for the quarter ending December 31st, 1883, and that an interim dividend of 2s. 6d. per share in respect of profits for the quarter ended September 30th last, with a bonus of 1s. for the half year on the ordinary shares, free of income-tax, will also be paid, making a total dividend for the half year at the rate of 6 per cent. per annum.

THE CABLE TO SOUAKIM.—The correspondent of the *Daily News* telegraphed from Alexandria, on Friday, the 14th inst., as follows:—"The Egyptian Government and the Eastern

Digitized by Google

Telegraph Company have agreed to terms for placing Souakim in telegraphic communication with Suez. The 'Chiltern' sails from Suez to-morrow to lay the cable to Souakim, and in a few days Cairo will possess the immense advantage of daily reports from Eastern Soudan." The *Standard* correspondent, however, telegraphing from Cairo on Tuesday night, stated that the contract for laying the cable had not then been signed.

In Liquidation.—The affairs of Mr. George Hawkes, of No. 9, Victoria-chambers, Westminster, and of No. 80, Gray's Inn-road, and Downford, Mayfield, Sussex, and late of Cressingham House, Sutton, Surrey, and No. 15, Brunswick-square, Brighton, and Richmond House, Kew, and Saint Winifred, Salisbury-road, Brighton, and No. 4, Stafford-terrace, Kensington, and Harwood House, Upper Norwood, and No. 5, Cheniston-gardens, Kensington, and of Summer Hill House, Bettws-y-coed, North Wales, inventor and patentee of electric light apparatus, are in liquidation. A general meeting of creditors has been called for the 31st inst., at Messrs. Lumley's, 37, Conduit-street, W. Mr. Hawkes was the patentee of the Hawkes arc lamp.

The Cost of Messages to Australia.—The Postmaster-General of New South Wales recently suggested to Mr. Berry that the colonies which subsidise the Eastern Extension Telegraph Company should still further endow them, in order that a reduction might be made in the cost of messages to and from Europe and the East. The extra cost was estimated to be between £60,000 and £70,000. The matter was considered by the Cabinet, and Mr. Berry has replied that Victoria will readily acquiesce in the proposal if all the colonies are required to pay their share of the loss. Under the present arrangement, Queensland, Tasmania, and New Zealand do not subsidise the company, and ministers think it would be very unjust if those colonies now joined in the compact should be further taxed in respect to the service.—*Colonies and India.*

Special Tool for Electric Plant.—Messrs. William Collier and Co., of Salford, have in hand for Messrs. Mather and Platt, of Salford, a special tool for the boring out in duplicate of the blocks for electro-magnets. This tool consists, says the *Iron and Coal Trades' Review*, of a boring machine with a long bed, carrying a head-stock in the centre, which is driven by a steel worm wheel connected on to the spindle. The machine is so arranged that a boring bar is fixed at each end of the spindle, and by this means it is boring from both sides of the head-stock simultaneously. It is provided with two carriages, with slots in the table for fixing the blocks to be bored, and the tables are provided with self-acting motions and separate screws for forcing the work up against the boring cutter, fixed in the boring bars, which are stationary. This machine in all its parts is exceptionally massive and powerful for taking very heavy cuts.

Discovery of Electro-Magnetism.—Some few months ago Dr. Tommasi once more raised the question, in the pages of *Cosmos Les Mondes*, did Œrsted or Romagnosi first discover electro-magnetism? Dr. Tommasi suggested that the electricians then about to meet at Vienna should endeavour to clear up the matter once for all. Captain Francis Lund, of the Danish navy, and one of the Danish Commission sent to Vienna, laid the question before Professor Holten, Professor of Physics at the Copenhagen University, and he asserts that Œrsted was unquestionably the first to discover electro-magnetism. M. Valette adds to the Professor's letter containing his reasons for coming to this conclusion, that he entirely agrees with Professor Holten. He states that he has repeated Romagnosi's experiments, being guided by the description of them given by Isarn, and published in 1802, and that they confirm Professor Holten's view of the matter.

International Health Exhibition.—It has been determined to open an exhibition in London on the 1st of May next, which shall comprise all those sanitary arrangements—and their name is legion—which have of late years been found, theoretically, to be so necessary to our existence. There will also be shown various systems of illumination, amongst which electric lighting is reckoned. Whether the exhibition buildings are to be lighted by electric light or gas we do not know. Probably some sort of competition will be arranged, and certain sections lighted by what the gas journals fondly term "the light of the future," whilst others will be lit up by gas. Whichever way the matter is settled, we hope managers of electric light companies will not forget our advice, given in a recent note, to do no more mere advertisement business. The electric light, we hold, is worth having and paying for, and to spend money where you might receive it is sheer folly. Shareholders will no doubt remember this.

The Recent Storm.—From Germany we learn that the terrific storm which passed over England in the early part of last week also visited with great force the coasts and other parts of that country. Much damage is reported to have been caused to property, in the neighbourhood of Emden a dyke having given way and the town being for some time in danger of being flooded. The telegraph line between Emden and Norden, connecting London with Bremen and Hamburg, as well as that of the Indo-European Telegraph Company, were either partially or totally interrupted for two or three days. Communication by the German Union Company, *viâ* Greetseel to Borkum, was, of course, safe, the company having, at the time of laying their cable to Valentia, replaced their aerial lines by an underground cable. Doubtless we shall shortly hear that the German Government have decided to render direct communication between the above mentioned places and London more safe by laying an underground cable to Norden.

The Mid-London Electric Railway.—The inhabitants of Oxford-street are organising a powerful opposition to the Bill for this proposed railway. They are afraid that if the necessary powers are obtained their business may be interfered with by the works in the same way that tradesmen in Cannon-street have had to suffer through the extension of the Metropolitan Railway from Aldgate to the Mansion House. It was stated at a recent meeting of Oxford-street tradesmen that the Bill included powers to use means of propulsion other than electric and hydraulic; and fear was expressed that the promoters might, after all, introduce steam, and with it ventilators. The engineer charged with the construction of the line has already stated publicly that no ventilators will be required, and that the works will be carried on entirely underground excepting at the proposed stations; but, nevertheless, the opponents of the Bill are not satisfied, and a guarantee fund has been formed to enable a fight to be maintained.

A Serious Accident in Baltimore.—In Baltimore, a few days since, Mr. Thomas Dwyer, foreman of a gang of workmen who were stretching a wire of the Bell Telephone Company across Davis-street, corner of Monument-street, had a narrow escape from death. He had hold of a section of wire which one of the workmen was trying to fasten to the top of a pole. The wire fell from the man's hands across a wire of the Brush Electric Light Company. In an instant, says the *Electrical World*, Dwyer, who was standing on damp gronnd, received a powerful electric shock which felled him to the ground. His hands were blistered, and he com-

Digitized by Google

plained of a terrible burning sensation from his stomach to his throat. Mr. Andrew Speir was passing at the time. He tried to step across the wire, but his foot came in contact with it. The shock threw him violently into the street. A horse attached to a buggy was also tumbled by the shock. Since then large blisters have appeared on Mr. Dwyer's stomach and hips. His right arm is paralysed, and terribly disfigured. His attending physician, however, says it will return to its normal state.

Overhead Wires in Wandsworth.—At the last meeting of the Wandsworth Board of Works the question of overhead wires was again considered. It will be remembered that the hearing of the summonses taken out by the Post Office against the Board because the latter would not allow them to fix further overhead telegraph wires was adjourned by the magistrate with a view to the parties settling which wires should be objected to and which permitted. The General Purposes Committee of the Board accordingly drew up a report which they presented to the above-mentioned meeting. They stated that they had again considered the subject, and recommended that the magistrate be informed that the Board are of opinion that, inasmuch as he is the judicial authority appointed by Parliament to settle the differences in question, such differences shall be settled by him after due consideration of the evidence which has been given on both sides, and that in the event of his sanctioning all or any of the proposed posts or wires, the site and line of each should be definitely fixed by his award, the Board still declining to take any responsibility in the matter. The report was unanimously adopted.

Coal Gas, Water Gas, and Electric Light.—The illuminating folks have grown very quarrelsome; and at present there is a triangular fight going on with the water gas, the coal gas, and electric light advocates as mutual antagonists. It is amusing to read in the gas journals the horrible tales of accidents and of destruction to health, eyesight, and complexion resulting from the use of either the rival gas or the electrical system of lighting. The prices, too, seem to bother them very much. The complaint made against Edison by the gas makers is first, that his light costs too much, and, second, that he charges too little for it. But if this complaint is true they ought to possess their souls in patience, for he cannot be expected to stand it very long. The coal gas representatives having been beaten by water gas in cost, attack it as extremely dangerous, and the cause of most of the accidents by suffocation. This is "important if true," but it must be confessed that the water gas advocates have just as pretty tables of figures the other way, and between them all these lighting companies manage to leave us as much in the dark as ever. There is room for all of them, however, if they will be content with moderate profits. It is the charging of too high prices that attracts rivals into the field.—*Philadelphia Ledger.*

Electricity under Discussion.—The mere mention of electricity or electric light at a meeting of those honest folk who occupy seats on a town council or local authority seems sufficient to set them all by the ears. Some of them are deeply attached to the "electric fluid," as they see it called in the local journal; others hate the sight of it in print, or transformed into light, energy, or anything else, though they would perhaps miss the telegraph. There was what is called an "exceedingly stormy meeting" at Hove on Monday last, the cause of which was a memorial from the inhabitants to the Improvement Commissioners, asking the latter to look with favourable eyes on the construction of a tramway to the West Brighton Station, and to the Brighton Terminus, the said tramway to be worked by electricity. It appears that the commissioners had already refused to sanction the work, as being prejudicial to the interests of the district, and calculated to drive away both visitors and residents. The reception of the memorial was warm in the extreme. The opposite parties were very highly charged, too highly in fact, for the insulation, which, in the shape of good temper, should have kept them apart, and the meeting ended in confusion. The introduction of electric tramways into Hove will evidently be attended with difficulties.

Chilian Telegraph Statistics.—From statistics published it appears that the greater portion of the telegraphic business of Chili is under Government control. In 1880 there were 102 telegraph offices open to the public, the total number of sets of apparatus being 178. The total length of lines opened up to date above mentioned was 5,700 (English) miles, inclusive of several military lines designed for that service in the Northern districts. In the year 1881-82 a new Government line to Ancud, in the island of Chiloe, with twelve stations, was opened. The length of this line is 473 (English) miles. The number of telegrams dealt with in the year 1880 was 258,684, with a total of 5,990,525 words. Two private lines exist between Santiago and Valparaiso, the one the property of the West Coast of America Telegraph Company, the other a line connecting Valparaiso, Santiago, and Buenos Ayres, belonging to the Monte Videan Telegraph Company. The last-named line was constructed in the year 1872, and placed Chili in direct telegraphic communication with Europe. In the year 1881-82 a project was laid before Congress to duplicate all single lines, and it is estimated that this will cost about £75,000, the length between the most northern and southernmost telegraph stations in Chili being 2,000 miles.

The Jablochkoff Company.—In the Chancery Division of the High Court of Justice on Saturday last, before Mr. Justice Pearson, a petition was presented by a holder of nineteen £5 shares, and a creditor for £43 15s., to wind up this company on the ground that it was unable to pay its debts. His lordship said that two petitions had been already presented to wind up this company on the 9th of November; one by a creditor named Willing, and another by a shareholder named Pennington. Mr. Willing's debt was paid shortly after his petition was presented, and Mr. Pennington's petition was withdrawn. Under these circumstances the present petition was presented by Mr. Everitt, the present holder of nineteen £5 shares in the company, and Mr. Dovey, who was, at the time the petition was presented, a creditor for £43 15s. for rent. It appeared that a cheque had been sent to Mr. Dovey for this sum on the 16th of November; he did not return the cheque, but declined to present it for payment, though there was no reason to suppose it would not have been paid, if presented. There seemed, therefore, to be no justification for the presentation of a petition by him. Then as to Mr. Everitt, he was the holder of nineteen shares; but he appeared to be the only shareholder who asked for a winding-up order. He was not supported by any of the other shareholders. The petition would therefore be dismissed with costs.

Fluidity and Conductivity.—Herr Carl Stephen, in an article contributed to the *Annalen der Physik und Chemie*, arrives at the following conclusions on the influence of fluidity on electric conductivity:—1. That the frictional coefficient of many mixtures of water and alcohol, as well as the electric conductivity of diluted solutions of various salts, can be readily estimated. 2. That the conductivity of diluted alcoholic solutions increases more slowly, when the amount

Digitized by Google

of salt is increased, than that of water solutions. 3. That the temperature co-efficients of the conductivity of diluted solutions correspond very nearly to those of the fluidity of the solvent. 4. That the conductivity of the alcohol and water solutions may be deduced from that of the corresponding water solutions by a factor which depends only upon the solvent, and is the same for different salts. 5. That if the proportion of alcohol is not greater than that of water the conductivity is very nearly proportional to the fluidity of the solvent. He gives the following equation, viz.:—

$$k = \frac{w\,K\,H}{w'\,\eta}$$

in which K represents the conductivity of a water solution of the same temperature and percentage as an alcoholic solution with which it is compared; H and $\eta$ the internal frictions of the water and of the alcoholic fluid for the same temperature; and $w$ and $w'$ the percentages of water in the alcoholic solution and in a mixture of alcohol and water of minimum fluidity.

Electric Lighting in Berlin.—Dr. Stephan, the Postmaster-General of Germany, lately paid a visit to the Central Telegraph Station in Berlin, for the purpose of inspecting the lighting by electricity of the instrument room. The work of fitting up and supplying the necessary plant has been carried out by Messrs. Siemens and Halske. The instrument room, which has an area of 880 square meters, is lit by seventeen arc lamps; the lamps are placed in advantageous positions, and an excellent light is given in all parts of the instrument room. The telegraphic apparatus in use here consists of 213 instruments, including 48 Hughes type writers and 165 Morse instruments. The air in the room now that gas is no longer used remains pure, and the temperature moderate. With gas lighting 121 jets were required, 20 for general purposes, and 101 for the lighting of the large instrument table. The air was oppressive and close, and, notwithstanding suitable ventilation, a very high temperature was maintained, which frequently rose to a maximum of 22° Reaumer. In consequence of the electric lighting this maximum has been greatly reduced; during the months of November and December it had fallen to 15° Reaumer. The air being purer and temperature reduced renders a lengthy duty for the clerks less irksome than heretofore. The motive power is supplied by two engines, near to which a third is placed as a reserve each of the engines drives two dynamos, by each of which five lamps are fed. Altogether there are four generators and 20 lamps (17 in instrument room and three in other departments) in use. The engines are fitted with good governors, so that unsteady driving may be avoided and a steady light be given by the lamps. The lamps are turned on at dusk, and employed till midnight, after which lighting by gas is resorted to.

New Verification of Joule's Law.—M. Alfred Reinisch writes in the *Zeitschrift des Electrotechnischen Vereins in Wien* as follows:—When we wish to use lead wire as a safety plug in an installation of arc or incandescent lamps, it is necessary to ascertain what current a wire of a given section will stand before fusing. In practice we content ourselves with allowing eight amperes as a maximum current per square millimetre of section of lead wire, and we adopt as secure a wire of two or three times larger section. Suppose, for instance, the case of an electrolier with 30 Swan lamps on it, each receiving a current of 1·4 ampere, it would be necessary, to be trebly secure, to adopt a lead wire of 15·95 square millimetres in section. It has been thought convenient to always maintain the same section for the lead wire, whilst varying its length. To this end different lengths of this wire, of two millimetres diameter, have been submitted, to varying currents, and the mean values of the number of amperes required to fuse a length of wire determined, as follows:—

| Length. | | Current. |
|---|---|---|
| 100 millimetres | ..... | 38·74 amperes |
| 90 „ | ..... | 39·38 „ |
| 80 „ | ..... | 40·01 „ |
| 70 „ | ..... | 41·24 „ |
| 60 „ | ..... | 43·60 „ |
| 50 „ | ..... | 46·91 „ |
| 40 „ | ..... | 50·01 „ |
| 30 „ | ..... | 56·80 „ |
| 20 „ | ..... | 66·84 „ |
| 10 „ | ..... | 87·35 „ |

By taking the lengths as abscissæ and the amperes of current required to fuse the lead as ordinates, a hyperbolic curve is obtained which is similar to that obtained by Joule's law, and the latter is therefore confirmed anew.

The Daft Electro-motor.—Some further details of the trial of the Daft motor at Saratoga, U.S., last month, alluded to in a note in last week's issue, is contained in the following cutting from the the *Engineering and Mining Journal* of New York:—"Mr. Daft, by a subdivision of his dynamo, claims to obtain a current of such low tension that all danger from contact is avoided; but the insulation was by no means thoroughly effected by his sending the current through a third rail in the centre, of which the fastening spikes were removed from the rail by a strip of vulcanised rubber. Then, although one could touch the rails without feeling any unpleasant shock, it was very evident that many were temporarily 'excited' in crossing the tracks on the occasion referred to, while no less than four horses fell on the track from the effect of the current, and had to be helped off. The actual performance consisted in the hauling by a two-ton motor of a five-ton car, with probably five tons more in weight of passengers, a distance of a mile and an eighth. This was up a grade of 70 feet to a mile, with one sharp curve, and was effected in eleven minutes. On the return, the motor was thrown from the track, and several who were on it had narrow escapes; but the accident was due to a make-shift rope coupling, and did not involve Mr. Daft's principle at all. The dynamos at the factory for generating the current were 500 feet from the track, and were operated by a 30 horse-power engine. The motor itself seemed entirely too small and light for the work expected from it, the dynamos thereof and connections occupying a box only about four by six feet. The current for these is taken up from the central track by a contact-wheel, which transmits it to a receiving dynamo, and thence, by connection with a steel belt through the axles to the outside rails, causes the revolutions. The apparatus is easily operated, and evidently was entirely under control. Mr. Daft was warmly congratulated on the degree of success obtained, and most of the numerous party present were confident that the trial was a proof of the practical success of the system."

Electric Lighting at St. Etienne.—The Lyons Electrical Power Storage Company have completed an installation in St. Etienne, France, of which *L'Electricien* gives the following details:—The motive power is derived from a water wheel actuated by a waterfall on the Furens, which flows past the town. The generating station is situate in the Rue du Bas Vernay, in the basement of a factory where the above-mentioned water-power has for some time past been utilised by the proprietor, M. Breuil, for gun-making purposes. About $3\frac{1}{2}$ horse-power can be spared for the work of generating electricity, which is accomplished by a Siemens D$^2$

Digitized by Google

machine. Two cables go from the dynamo to the Café du Square, Place de la Badouillère, where the accumulators are placed. Another cable leads from the batteries to the different places where the lamps are fitted, and back to the generating station. In the latter there are two incandescent lamps, in the café 24 lamps, and other lamps in other houses, besides which the current is led to a small motor which works a velvet ribbon machine. Altogether there are 34 Swan lamps in circuit. The total length of the circuit is 1,200 metres. The dynamo gives out 51 volts and 30 amperes. The $3\frac{1}{2}$ horse-power furnished by the waterwheel is not enough to run it at its best speed, and it gives too great electromotive force, and not enough current for use in the lamps; nevertheless, thanks to the accumulators, 34 lamps can be worked at the same time as well as a small motor, which altogether would require a motive power of $5\frac{1}{2}$ horses if they were run direct off the machine. The accumulators, 80 in number, have 12 plates, and weigh 40 kilograms. For lighting work, 69 are used, which are divided into three series of 23 cells each, the motor requiring a fourth series of cells, and the others being used solely to replace other cells. For charging, these accumulators are divided into four series of 20, the normal time occupied in this work being 30 hours, which, with a current of 30 amperes, represents 3,240,000 coulombs per series. According to figures supplied by the company, the time of discharge whilst supplying a constant current of 45 amperes is 14 or 15 hours. The charge is, however, far from being exhausted in practice, as the lighting is not maintained for more than six hours, from 6:30 p.m. to 12:30.

A Defective Lightning Conductor.—The following very interesting and instructive letter appeared in a recent issue of *The Times* over the signature of "John W. Burgon." It relates to a defective lightning conductor attached to Chichester Cathedral, and which, instead of protecting that building during a recent thunderstorm, was not very far from aiding in its destruction. The letter runs as follows:—"A storm burst with unexampled fury over this city (Chichester) at about 1:30 in the morning of Monday, the 26th ult. The vividness of the lightning, the sharp rattle of the thunder, like the discharge of musketry, the fierce hail, and tempestuous wind which followed, will not easily be forgotten. Early on Wednesday it became known that the lightning conductor on the spire of the cathedral had been shattered and partially fused. A lady who lives opposite, and was watching the storm, compares the impact of the electric fluid to the explosion of a rocket. This incident has excited so much public attention that I venture ask you—if you think the matter of sufficient interest—to give insertion to the present letter. The nature of the accident was scientifically investigated last Tuesday by two parties of eminent electricians—Major R. Y. Armstrong and Captain Philip Cardew, of the Royal Engineers; Dr. R. J. Mann, F.R.A.S., ex-president of the Meteorological Society, and Mr. Anderson. Finding that they were all four entirely agreed on the subject, I requested one of their body (Dr. Mann) to favour me with a written report. He has obligingly sent me the following statement: 'The lightning conductor was put up sixteen years ago, when the new tower and spire were erected after the fall of the old one. The conductor is one of now obsolete form, which was known at that time as Pratt's patent. It consists of twelve No. 15 gauge copper wires, placed side by side, and connected together by a zinc wire crossing the copper wires from side to side in a continuous zigzag. The conductor was not materially injured for about 40ft. downwards from the terminal point. It was then scattered into short fragments of copper wire about half an inch long, or broken into contorted and twisted-up fragments, for another 100ft., until it reached the lead flushing of the roof. Below that, it was not materially injured. But a rain-water pipe, descending from the roof of the transept, and about 12ft. or 15ft. from the conductor, and consisting of successive joints of lead pipe finally carried into one of the ordinary iron rain pipes, was broken where the iron pipe received the lead. About 4in. or 5in. of the iron pipe was shattered and scattered into fragments, leaving a clear gap. The cause of the accident is quite manifest. The conductor was not of sufficient capacity for its work. It weighed only $10\frac{1}{4}$oz. to the yard. It was also of essentially bad construction. The copper wires had been materially injured by galvanic action, set up and gradually carried on, where they were crossed by the zinc wire traversing them from side to side. The breaking of the copper wires into short lengths was in all probability due to this cause. They were ruptured where they had been weakened and reduced by the galvanic action. The $1\frac{1}{2}$in. solid copper tape, $\frac{1}{8}$in. thick, which is the smallest conductor that should have been trusted for the protection of a structure of this height and size, weighs 36oz. the yard. The conductor was not injured below the roof of the transept and nave, because the lead flushing, and the water pipes connected with it along the side walls, had from that point begun to assist the conductor in carrying the lightning discharge down to the earth. That this had been the case was substantially proved by the damage done to the one iron water pipe. The earth-contact had been made by carrying the lower end of the conductor down into a narrow, bricked, well-like shaft, sunk into the soil of the old grave yard, about a dozen feet from the point where the descending conductor reached the ground. There was considerably greater resistance in this earth connection (about 70 ohms) than a well-appointed *paratonnerre* should have. This virtually increased the inefficiency of the conductor, but probably was of less immediate consequence than the very weak section of the conductor itself under the circumstance of the supplementary conducting power of the lead flushing and water pipes already spoken of. The conductor, inefficient as it was for satisfactory and permanent performance of its work, unquestionably rendered good service to the spire and tower in preventing mechanical mischief to the masonry there. The uninjured state of the upper stretch of conductor at the top of the spire is very remarkable. In all probability the terminal point of the conductor above had in some way assisted to relieve the tension there at the time of the discharge. The force of the discharge virtually fell upon the conductor lower than this, on the side of the spire. The disintegrating force is always most energetically exerted where, so to speak, the electrical blow falls. The breaking up of the copper wire into short lengths was very curious. It will be noticed how these short lengths correspond with the crossings of the waving zinc wire. I find nearly the whole of the fragments that I brought away have tapering and shelving extremities—not transverse fractures—as if they had been chemically corroded away there before the fracture.—Robert James Mann.' The sum of the matter is that this cathedral has providentially sustained no injury beyond the destruction of its lightning conductor, but the inefficiency of 'Pratt's Patent,' in the case of a building of this magnitude, has been made alarmingly apparent. I venture to think that wherever such a conductor exists it should be removed, and that a continuous solid band of copper tape (of the substance above recommended) should be substituted for it."

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 103.)

**Voltaic Series.**—The degree of power of generating a voltaic current differs with every different metal and liquid. The relative power of two metals is usually ascertained by connecting them with the ends of a galvanometer coil, then immersing the free ends of the metals simultaneously in the particular liquid, and observing the direction of deflection of the galvanometer needles. The strongest acting metal is electro-positive.

In this way numerous tables of what are termed voltaic series of metals in various electrolytes have been obtained, which differ somewhat with every different liquid, and also with the same liquid of different temperatures or strengths, but are usually approximately in the above order. For the order in any particular liquid the reader is referred to text books on electro-metallurgy, and to special researches on the subject. Extensive series may be found in "Gmelin's Handbook of Chemistry," Vol. I, p. 397; also *Proc. Roy. Soc.*, No. 200, 1879, pp. 38-49; and in "Electro Metallurgy," Longman's Text Books of Science.

The above series are only those obtained by immersing two different metals in one liquid; others are obtained by immersing two pieces of the same metal in two different liquids separated by a porous partition; and more complex ones might also be formed by immersing two metals in two liquids thus separated; and series may also be obtained by the employment of fused electrolytes in place of the usual aqueous solutions.

**Voltaic Batteries.**—Voltaic elements are simply combinations selected from series arrived at in the above manner, those being selected which include the best combination of desired qualities, such as strength of current, cheapness of metal and liquid, manageability, freedom from offensive fumes, &c. A strong element can only be obtained by selecting metals which are far asunder in the "series." The strongest are those formed of two metals and two liquids. The varieties of batteries are very numerous, and a complete description of them would fill a volume.

**Voltaic Currents.**—The continuous union of the two electricities, or electric states of positively and negatively charged substances, through a conductor, constitutes an electric current; and the chief circumstances to be considered in connection with such currents are polarity, potential, electromotive force, quantity, strength, and density of current, conduction, resistance, polarisation, &c.

**Polarity, Potential, Electromotive Force, &c.**—Assuming the Ceaseless Molecular Motion Theory of voltaic (and chemical) action to be the correct one, we may consider the pre-existing molecular vibrations of the metals to be the cause of volta-static polarity and all its consequences; that when two different metals are brought into mutual contact, the molecular motions of the two metals act upon each other; and the composition of forces causes the one metal to become positive and the other negative; also that, when a metal is brought into contact with an electrolyte, similar effects of polarity occur.

Previously, therefore, to the completion of the circuit and formation of a current, the two metals, by contact with an electrolyte, become charged with the two kinds of electricity in a statical condition, and are in a state of electric potential or pressure, capable of doing electric work by their subsequent discharge. This difference of electric potential produces electric flow, like a difference of pressure of water produces a flow of that liquid. The electric charges of the metals are in a state of tension tending to escape, and may be detected by means of an electroscope, or measured by an electrometer; the degree of tension is, however, exceedingly minute. The charged state also produces induction, which acts from molecule to molecule during discharge, and precedes current.

Electromotive force, or the power which moves, or tends to move, electricity from one place to another, varies with every different voltaic couple, and with the same couple at every different temperature; and these differences may be detected by opposing the two couples to be compared, in single series in circuit, with their terminals connected to those of a galvanometer; the current from the strongest then produces a deflection of the needles. In a voltaic series, the metals are arranged in the order of their relative degrees of electromotive force.

The degree of electromotive force of a couple depends considerably upon the degree of difference of strength of chemical affinity of the two metals for the electro-negative elements of the liquid; and the farther asunder the metals are in the chemico-electric or volta tension series, the greater usually is the electromotive force of the current they produce. All other circumstances being alike, the most rapidly corroded metal, used with the least corroded one, usually gives the current of greatest electromotive force.

The measurement of the degree of electromotive force of a voltaic cell is usually made by comparing it with that of some convenient and steady source of current, such as that of a Daniell or a Clark cell. The unit of electromotive force (E) is termed a volt, that of a Daniell cell is = 1·078 volt, and that of a Clark = 1·457volt. For measuring feeble electromotive forces I have devised a convenient form of thermopile, consisting of about 300 pairs of iron and German silver wires, and have employed it in making a great number of measurements, not much exceeding that of one Daniell. It is capable of measuring differences of $\frac{1}{38\,000}$th of a volt. (See *Proceedings of the Birm. Phil. Soc.*, Vol. IV., Part 1.)

**Resistance.**—Every conductor of electricity, no matter how good it may be, is an obstacle to the passage of a current. Electrolytes offer great resistance, especially with anodes composed of a metal which does not readily dissolve in them. Perfectly pure water with platinum electrodes hardly transmits any current from a single voltaic cell. The degree of resistance of a saturated solution of sulphate of copper at 48°Fahr.—and this is a comparatively good conducting electrolyte—is nearly 17 million times that of a copper wire of equal length and section at 32°Fahr. Tables of the conduction resistance of various liquids are contained in most works on voltaic electricity.

According to Quincke ("Pogg. Annalen," Vol. CXLIV., pp. 1-33, 161-190), as long as the density of the current in the liquid is too small to overcome the chemical affinity the liquid will behave as an insulator, but it may become conducting by an increase of that density. Liquids conduct, according to Ohm's law, the same as solids (*Journal Chemical Society*, 2nd series, Vol. X., p. 208).

The total resistance in an electrolytic circuit is usually divided into internal, or that in the battery, and external, or that in the remainder of the circuit; there is resistance in the battery itself, in the liquid, and especially at the surface of the negative plate, if hydrogen is evolved there.

The ordinary unit of resistance (R) is termed an ohm, and is that offered at 0°C. by 1·0486 metre length of mercury of 1 square millimetre section. The amount of resistance in a wire, A, is conveniently measured by dividing the current from a very small Daniell cell, so that one portion shall pass through A and one wire, B, of a differential galvanometer, and the other portion through another wire of known resistance, C, and the other wire, D, of the galvanometer in the opposite direction to that through B, and altering the length of A until the needles of the instrument stay at zero. The resistance in A and C is then equal. The measurement of resistance of an electrolyte is much more difficult on account of the varying polarisation of the plates, but may be effected in a somewhat similar manner by making two measurements by means of a very feeble current after the polarisation has become steady—one when the electrodes are near together, and the other when they are far asunder, using in each case electrodes as large as the transverse section of the liquid, and in certain cases of the same metal as that of the salt of the electrolyte in order to diminish polarisation. The difference of resistance of the

Digitized by Google

two measurements is the amount of resistance of the difference of length of liquid in the two cases.

Strength of Current.—The strength is the amount which flows through any transverse section of the circuit in a given period of time, and the amount flowing at any given instant is the same in every such section of the circuit, whether that section be large or small; the unit of time employed is one second. It varies directly as the electromotive force, and inversely as the total resistance in the circuit (Ohm's law).

A given voltaic cell can only yield a certain maximum strength of current, and any conductor introduced into the circuit diminishes that amount. The greater the electromotive force of a current, the less is it diminished by increase of external resistance; such a current is said to possess "great intensity." If the external resistance is very small, an increase of electromotive force of the battery adds very little to the strength of the current; but if it is large, the opposite effect takes place. The difference of effect produced by means of a current from a single cell, and one from many, does not arise from any difference in the nature of the current in the two cases, but from the difference of proportion of internal to external resistance. No difference has hitherto been proved to exist in any two currents of equal strength.

The unit of strength of current (I) is termed an ampere, and is the strength produced by an electromotive force of 1 volt in a circuit having a resistance of 1 ohm. The strength (or quantity per second) of a current may be measured by passing the current during a known period of time, either by means of platinum electrodes through dilute sulphuric acid in a voltameter, and measuring the evolved hydrogen, or by means of silver electrodes through a solution of argento-cyanide of potassium, containing the minimum practicable amount of free potassic cyanide, and weighing the deposited silver. The latter method gives a little deficiency, owing to a small amount of the current passing through the free cyanide. Each ·000162 grain of hydrogen or ·017343 grain of silver deposited per second equals 1 ampere. Additional methods of measurement are usually described in text books on voltaic electricity.

Unit of Quantity of Current.—Whilst the degree of intensity of chemical action between two substances determines the electromotive force of the current, it is the quantity of substances uniting which determines its amount. The unit of quantity of current (Q) is termed a coulomb; it is one very little used, and is the amount which a strength of one ampere gives in one second. Measured by the method of electrolysis, it is that which deposits ·000162 grain of hydrogen, ·0051035 grain of copper, or ·017343 grain of silver.

Density of Current.—This means merely the strength of current passing through a given section of a conductor, or into or out of a given sized surface of electrode. No unit of it has hitherto been commonly recognised, but I have proposed (*Proc. of Birm. Phil. Soc.*, Vol. III., p. 277) the unit strength of current entering a surface of one square centimetre of cathode as a convenient one.

Density of current at the surface of the electrodes is one of the most important circumstances in electrolysis. Variation of it has often great effect both upon the physical structure and chemical composition of deposits upon cathodes; the former has already been described. It also appears to affect the properties of oxygen and chlorine when they are separated at the anode. Metals which are easily oxidised, such as cobalt, are deposited upon cathodes in a state of oxide or basic salt if the density of the current at that surface is small, but in the state of metal if it is great. It was largely by increasing the density of the current that Davy succeeded in isolating potassium. Any circumstance, such as polarisation, which diminishes the density of the current, is liable to affect the properties and composition of the deposit.

Quincke has shown that the force tending to separate the elements of an electrolyte is proportional to the strength of the current per unit of sectional area of the liquid; that it increases with the electromotive force of the current, and is inversely proportional to the length, but independent of the cross section and conductivity of the liquid, if the resistance of the remainder of the circuit is small in comparison with that of the electrolyte. (*Journal of the Chemical Society*, Vol. X., p. 208.)

## CURRENT ENERGY.—XI.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 57.)

Sir W. Thomson's thermo-electric theory was published in 1851, and, so far as linear conductors are concerned, in a complete form. His later papers (1854-6) contain a re-statement of the same in a somewhat simpler form, practical experimental results, and an extension of the theory to crystallised media, under which term are of course included isotropic conductors in a state of strain. In the meantime, under date 1853, the eminent German scientist, Professor Clausius had also contributed to the theory. Apart from certain speculations as to the origin of the E.M.F.'s, Clausius's theory amounted to this. At the places of contact of different metals there are E.M.F.'s of thermal origin, which vary in strength with the temperature, and in such a manner as to be subject to the second law of thermo-dynamics, *i.e.*, as regards the reversible heat-effects. Calling P the force from $a$ to $b$, P is a function of the temperature. Hence there is no current set up in a circuit of $a$ and $b$, if the junctions are equally hot, from the balancing of the E.M.F.'s, which can only produce a static effect. Destroy the equality of junction temperature, and a current is set up due to the difference between the two contact forces; and since the second law requires that the contact force shall vary directly as the temperature, the complete E.M.F. in the circuit is $E = p\,(t_1 - t_2)$, where $t_1$ and $t_2$ are the junction temperatures, and $p$ is a constant for the two metals.

This state of things Clausius regarded as representing the regular phenomena, the normal behaviour of a thermo-electric circuit, and he considered the departures therefrom, especially when high temperatures occur, as due to changes of molecular condition or of structure produced by alteration of temperature, in support thereof instancing the differences between hard and soft steel depending on greater or less velocity of cooling, they behaving as different metals both mechanically and thermo-electrically. He also quotes an experiment of Seebeck, who found a ring of antimony to behave as if of two different materials, and which on rupture was found to be structurally different in different parts. Also Magnus's result that currents in circuits of one metal had their origin in want of homogeneity. (To which we may add that a strained wire is thermo-electrically different to the same wire unstrained. But it does not appear that a merely qualitative specification of a strain, *e.g.*, that a portion of a circuit of one metal is stretched, is sufficient; for the current may go one way across the hot junction of stretched and unstretched parts under small tension, and the other way with greater tension. Here, however, it may be mentioned that in the first case the strain is elastic, and in the second that there is a permanent elongation of the wire as well.)

Clausius thought that differences of structure might occur in a homogeneous metal (homogeneous when at one temperature throughout) when unequally heated, and without developing this idea proposed to explain the departures from the regular phenomenon by means of the new E.M.F.'s diffused through the unequally heated and therefore structurally different parts of the separate metals, acting together with the ordinary Peltier forces at the junctions.

Superficially regarded, this would seem to be simply the theory of the Thomson effect in a rudimentary form. But there are in reality two distinct ideas involved. The first is that the thermo-electric power of a metal (that is, $p$ or $P/t$) may not be always constant, as in the supposed regular or normal phenomenon of Clausius, but may sometimes vary

Digitized by Google

with the temperature, thus introducing abnormal reversible thermal effects in the interior of single metals. The second is a hypothesis as to the cause of the abnormal variation of $p$, viz., that it proceeds from change of structure. Some reasons against this are given below. In the meantime we may remark that in a circuit of copper and lead, for instance, the hypothesis that the copper, along which the temperature varies, may be considered as being made up of an immense number of pieces of different metals, though only differing very little from one piece to the next, at whose junctions there are small forces of the same nature as the large terminal forces at the junctions with the lead, and that all the reversible heat effects thereby resulting are subject to the thermo-dynamic laws, does lead to correct expressions for the Thomson E.M.F. and the total E.M.F. in the circuit, when we proceed to the limit, and hence make the number of divisions infinite, and the changes of material infinitely small.

As we remarked before, Clausius did not develop his idea, but (*Mech. Würmetheorie*, Vol. II., Absch. VII.) he gives the development made by Budde in 1874. The supposed changes of structure are limited to be of a reversible character, so that heating a portion of a wire, and then cooling it back to its original temperature is always accompanied by a restoration of the original structure; that is, the structure must depend upon the temperature only, and thus be the same in all parts of a wire which have the same temperature, and not be permanently altered by heating. This excludes the irreversible changes of structure sometimes produced, as when the sudden cooling of steel does not restore the structure it possessed before heating, but results in something notably different.

Now, instead of $p\,(t_1 - t_2)$ being the sum of the terminal Peltier forces, as in the regular phenomenon, we shall have $p_1t_1 - p_2t_2$, where $p_1$ and $p_2$ are the now unequal values of $p$ at the junction temperatures $t_1$ and $t_2$. And in the copper we shall have small forces, owing to the gradual change of $p$, the E.M.F. between two consecutive pieces whose junction temperature is $t$, and whose values of $p$ differ by the amount $dp$ being $tdp$, so that $\Sigma tdp$ expresses the total Thomson E.M.F. Adding the terminal forces, attending to directions, their sum reduces to $\Sigma pdt$, where $dt$ is the small difference of temperatures between two consecutive pieces. Clausius's and Budde's theory leading precisely to the previously given results (Art. IX., Vol. XI. p. 558), nothing more need be said of it, save as regards the hypothesis made that the variation of the thermo-electric power of a metal with the temperature results from a change of structure.

To examine this, perhaps the simplest way will be to interpret Clausius's views with the help of the thermo-electric diagram. Consider that when the so-called regular or normal phenomena are present the lines of power of all the metals are *parallel* straight lines, which, if we take the line of the standard metal horizontal, will be also horizontal, at different heights above or below the standard line. The E.M.F. in a circuit of two metals will be represented always by a rectangle, viz., the area enclosed by the two horizontal lines of the metals considered, and by the vertical lines corresponding to the junction temperatures. The rectangle will increase in area at a uniform rate as the difference of temperature increases, and if we keep the cold junction at a constant temperature and heat the other, if the current in the circuit be represented by a line, such line will be straight.

Clausius's hypothesis, then, would imply that if the lines of two metals should at some temperature lose their parallelism, and either diverge or converge, we should have evidence of change of structure. The mere existence of slope in the lines of power would therefore imply change of structure, and departure from the regular behaviour. But this is very different from the experimentally found state of things. No two metals have their lines parallel. The lines of power have all degrees of slope—some up, some down. The regular behaviour is conspicuous by its absence; departures from it are the rule, and so far from these departures only coming into play with wide differences of temperature, the constancy of the slopes, *i.e.*, the straightness of the lines, shows that the supposed departures are in force at all temperatures, and within the smallest range of temperature. And the lines of current, instead of being straight, are parabolas. (*See* equation (4), p. 57. Let $t_2$ be constant, $t_1$ variable, E the ordinate, and $t_1$ the abscissæ of the curve required.)

It would appear, then, that to regard the changes of thermo-electric power with the temperature, which are universal and not exceptional, as evidence of change of structure is not justifiable. We should rather conclude that constancy (not absence) of slope implies constancy of structure; that if within a given range of temperature the line of a certain metal continues appreciably straight, whatever its slope may be, there is no appreciable change of structure, but that should it become curved, which is an exceptional phenomenon, we have real change of structure. This (curvature) we might anticipate to be the case at sufficiently high temperatures with the lines of all the metals, as it is well known that marked changes of physical state, as from solid to liquid, are not perfectly sudden. But this is quite a different thing from the change of structure going on at a uniform rate through hundreds of degrees C that we shall have if we adopt Clausius's hypothesis, which, by the way, is wholly unnecessary for the mathematical development of the subject.

The peculiar manner in which the expression for the integral E.M.F. in a wire, say copper, viz., $\Sigma tdp$, when added to the terminal junction forces with lead (taking lead for the metal paired with copper, in order not to have any E.M.F. except in the copper and at the junctions) becomes converted into $\Sigma pdt$, which represents the total E.M.F., is worth illustrating explicitly. We may remark, in the first place, that we cannot get any resultant E.M.F. in our circuit by supposing that the diffused force in the copper wire is due merely to the variation of the contact force with respect to lead at different parts, although such might be suggested by considering that if a piece of lead were brought successively into contact with different parts of the copper wire, if insulated from one another, it would in each case take a definite potential with respect to the copper, the difference of potential being equal to P, the Peltier force, whose amount varies as the temperature of the copper varies. Let the copper wire be divided into four pieces, for instance (the process is the same for any number), and let the values of P for them be $P_1$, $P_2$, $P_3$, $P_4$. The terminal forces when the copper is in circuit with lead will be $-P_1$ and $+P_4$, and the intermediate forces at the three junctions of copper with copper would, on our supposition, be $P_1 - P_2$, $P_2 - P_3$, and $P_3 - P_4$. But their sum is $+P_1 - P_4$, which exactly cancels the junction forces with the lead, and leaves us no resultant E.M.F. In fact, we have a case of force derived from a potential function, of which a characteristic property is that the integral force round a circuit is zero.

Nor do we, for the same reason, get any assistance by putting $pt$ for P in the above. But if, in the complete variation of $pt$, viz., $d(pt) = tdp + pdt$, we neglect the latter part, and sum up the former, $\Sigma tdp$, we get the integral force in the copper. And, neglecting the former part, and summing up the latter, we obtain $\Sigma pdt$, which is the resultant E.M.F. Dividing the copper into four parts as before, let the temperatures of the five junctions be $t_0$, $t_1$, $t_2$, $t_3$, $t_4$; and the values of $p$ be $p_1$, $p_2$, $p_3$, $p_4$ in the four pieces. Then the sum of all the forces is

$$-t_0p_1 + (p_1 - p_2)\,t_1 + (p_2 - p_3)\,t_2 + (p_3 - p_4)\,t_3 + p_4t_4,$$

where the first and last terms are the forces at the junctions with the lead, and the three intermediate represent $\Sigma tdp$, the integral force in the copper. Now re-arrange the terms, pairing the first with the first part of the second, the second part of the second with the first part of the third, and so on, and we get

$$p_1\,(t_1 - t_0) + p_2\,(t_2 - t_1) + p_3\,(t_3 - t_2) + p_4\,(t_4 - t_3),$$

*i.e.*, $\Sigma pdt$, the expression for the complete E.M.F. in the circuit.

Reckoned per unit of length, the force in the copper is $t\frac{dp}{dx}$ in the direction of decrease of $p$. When we arrive at the junction with lead, we have an abrupt instead of a gradual change of $p$, so of course we cannot reckon the force per unit

Digitized by Google

of length, but must take it in the lump, viz., *tp* or P, the Peltier contact force, the only proved contact force between metals which do not act chemically on one another.

(TO BE CONTINUED.)

## MODES OF TRANSMITTING POWER.

Many of our readers may be aware that the town of Geneva has recently undertaken an extensive enterprise for the utilisation of the waters of the River Rhone. The magnificent current which sweeps through the city is well known to tourists, and its utilisation offers a fair field for industrial enterprise. It may, however, seem astonishing that the governing body of a city should have undertaken such a task. This is, in great measure, due to the fact that of late years the Rhone, in spite of its depth and width, has not been found sufficient to carry off in periods of flood the surplus waters of the Lake of Geneva. The lake has risen in consequence by several feet, and considerable damage has been caused thereby. Litigation, the usual result of such damage, has followed, and the town of Geneva has thus had the question of improving the condition of the river on which it stands practically forced upon it. Its citizens are giving proof of their wisdom in combining with it a scheme for the utilisation of its waters, which, it is to be hoped, will turn what might have been a mere costly operation into a real source of wealth for the town.

The general plan of the project is to erect a turbine house, with a large series of turbines, on one of the arms made by the Rhone in passing round the well-known island lying at its outfall from the lake. The other channel will be much deepened by dredging and other means, and the total discharge of the river will thus be materially increased. With these arrangements we have nothing to do; it is when the power has to be taken from the turbines for industrial purposes that the interest for electricians begins. It is proposed to transport the power into the heart of the city, and there to let it out to manufacturers of any description who may be willing to pay for it. In determining the means of transport which shall be employed, the technical committee have had before them the various systems of transmission, by wire rope, by compressed air, by water pressure, and by electricity. In the report lately presented, in the name of the committee, by their president, M. Turrettini, these questions are discussed, and of this part of their report (which is in itself a very valuable document) we propose here to offer a brief account.

The first systems to be considered, being at once the simplest and most ancient, are those by belt and pulley, by gearing, or by shafting. But the small distance to which these can be extended puts them at once out of court. We may therefore pass on to the system of transmission by wire rope invented about 1850 by M. Hirn. Here wire ropes running at a speed of 70 to 80 feet per second (say 50 miles an hour) pass over a series of vertical pulleys and round two large pulleys, one at each end of the circuit. Of these two pulleys, one is connected with the turbine or other motor and drives the rope, the other is driven by it, and is connected in its turn with the shafting of the manufactory to which the power is supplied. This method of transmission has been much extended in Switzerland during the last fifteen years, and has certainly done good service. Its applications at Schaffhausen, Fribourg, and Bellegarde are well known. It is, however, by no means the simple and inexpensive matter which it seems at first sight. The pulleys must be placed on the top of lofty standards, made in iron or stone; their distance apart can never be more than about 200 yards, and must often be less, according to the configuration of the ground. Again, the wear and tear of the ropes is so severe that they require to be changed almost yearly; moreover, when first started they elongate considerably, and thus have to be shortened and spliced up at frequent intervals, for which skilled workmen and various mechanical facilities are necessary. The rope occasionally breaks; and this, especially where they cross high roads, may produce serious accidents. Lastly, there is no means of measuring the power transmitted, so that the system is only applicable where this power is large, and where it has not to be broken up amongst a number of consumers.

Compressed air as an agent for transmission has also come largely into use within the last few years. Its first application was due to M. Colladon, who employed it for tunnels, especially at Mont Cenis. On this system the turbines or other motors work air-compressing machinery, which forces air into reservoirs under high pressure. The air thus reduced in volume is conducted in metal pipes to the different points where power is required. Since the loss in pressure in the pipes is very small, they need only be of moderate dimensions, even where the power to be transmitted is large; hence, in such cases as tunnelling, where the useful effect is of secondary importance, this system offers many advantages. But this useful effect, mainly through the loss occasioned by the heating and cooling of the air, cannot be estimated at more than 50 per cent. as a maximum; and this, for such cases as the present, forms a fatal defect. Again, the ice, which forms at the outlet for the air after it has done its work, is apt to choke the passages, and becomes a serious difficulty. This has been overcome either by the injection of steam into the expansion cylinder, or by heating this cylinder externally; but this necessitates the expense of a steam boiler with its attendant at the point where the air is utilised, and thus destroys one of the special advantages of the system.

With regard to electricity, the report observes that this system of transmitting power is now the subject of very vigorous discussion, and that there is every reason to believe that before very long it will have vindicated itself against all the objections urged by its opponents. On this system, as is well known, the turbine or other motor works a dynamo electric machine with continuous current, called the generator. The electricity thus produced is conveyed along a wire to the point where power is required, and there causes rotation in a similar dynamo machine, called the receiver. This last machine works the shafting of the manufactory. The system is thus a very simple one, but the losses in the transmission are considerable, being due mainly to the heat produced by resistance in the two dynamo machines and the connecting wire. So great are these losses that the well-known experiments of M. Deprez showed a useful effect of only 30 per cent.; in that case, however, there were difficulties which have since been overcome, and the distance transmitted was about 5 miles, which is much greater than would be needed at Geneva. Messrs. Siemens are now constructing machines with a tension of 500 volts (which is sufficiently low to prevent the risk of accident), and these machines have an efficiency of at least 80 per cent. The joint efficiency of two such machines is therefore 64 per cent.; and deducting 10 per cent. for loss in the cable we should have a useful effect of 54 per cent. given off at the shaft of the receiving machine.

Take the case of a machine with a tension of 500 volts, and transmitting a power of 50 amperes, or say 33 horse-power; then with a distance of 1 kilo., and with a copper wire having a resistance of $\frac{1}{2}$ ohm per kilo., we may count on giving off 23 horse-power on the shaft of the receiving machine.

The price of the copper wire with its coating of lead would be about 2,500 francs per kilo.; and, adding that of the two machines, the first cost per kilo., including erection, may be set down at 15,000 francs. Allowing 15 per cent. for interest and depreciation, this would give a cost of 55 francs per horse-power per annum, and making allowance for the cost of maintenance, oil, &c., it would be fair to take 100 francs (or say £4) per annum as the cost per horse-power of transmitting not less than 20 horse-power to a distance of about $\frac{3}{5}$ of a mile.

These figures, as the report observes, show that the moment should not be far distant when electricity may be employed with advantage for such purposes; but they consider that the safety and durability of the dynamo machines

Digitized by Google

is not as yet sufficiently assured to warrant them at this moment in adopting electricity as an agent of transmission on so large a scale.

Lastly, we have the mode of transmission by water pressure, which has been finally preferred by the committee. The special advantage which they point out in its present application is that it gives the means of measuring exactly the quantity of power consumed at any particular spot, by simply measuring the water passing through a meter attached to the delivery pipe. Such measurement is impossible in the case of wire ropes or compressed air, and though it may be possible in the case of electricity, the measuring instruments are too recently invented to have the sanction of experience. At the point of consumption the pressure water may be utilised by two different methods. The first is that of a turbine or tangential wheel, which uses the kinetic energy of the water, and which has an efficiency of 70 per cent. at most. The other is the ordinary water engine, with piston, cylinder, and crank, which gives an efficiency of 80 or even 85 per cent. On the other hand, its price is greater than that of a turbine of equal power, and it has the disadvantage that with a given velocity the consumption of water must also be constant, however much or little may be really required. With a turbine, on the other hand, the pressure water expended may vary with the power needed. The water-engine, however, may itself be used as a meter, since, the number of rotations and the volume per rotation being known, the quantity can at once be determined. The turbine requires that a water meter should be employed, occasioning some loss of power, and therefore of efficiency.

Transmission by water pressure requires somewhat expensive pipes, the cost being larger as the pressure is less; and since the friction of water in pipes depends only on velocity and not on pressure, it follows that the system is more economical the higher the pressure at which it is worked. The committee proposes a pressure equal to 100 metres head, or say 150lb. per square inch. Their reason for this relatively low pressure is that the system will probably be completed at some time by establishing a reservoir at some high point above the town, and that the greatest heat given by such a reservoir would not be more than 90 metres.

Whilst the first cost of the pipes is greater than that of a wire cable, it must be remembered that the loss due to friction in the former does not vary as the diameter of the pipes, and thus to increase the diameter of a pipe will enable it to increase the power delivered much more rapidly than in the case of a rope. It must be added that transmission by water loses many of its advantages if the point of consumption is on a level higher than that where the water is compressed, since the pressure is diminished in proportion to this loss of head.

With regard to cost, a work by M. Beringer on transmission by electricity gives the following figures:—To produce 5 horse-power by a small steam engine costs per horse-power per hour 0·40 franc. To produce 10 horse-power by a moderate-sized steam-engine costs 0·27 franc, and to produce 50 horse-power by a large steam-engine costs 0·106 franc, or possibly still less with very large engines of the best construction. With gas engines the cost varies, of course, with the price of gas; at Geneva it would be about 0·40 franc. Lastly, assuming that 100 horse-power is obtained from a natural head of water, and is to be transmitted for 5 kilo., the price per horse-power per hour on the systems considered above may be taken as follows:—

| | |
|---|---|
| Wire rope ..... | 0·029 franc. |
| Compressed air ..... | 0·037 franc. |
| Electricity ..... | 0·027 franc. |
| Pressure water ..... | 0·045 franc. |

If these figures are correct it would seem that the water transmission is the most costly; nevertheless, for such a case as the present the committee considers that this evil is outweighed by its security in working, convenience in distributing, and general safety. Moreover, the water is not only applicable for motive power, but may also be used for many other domestic or industrial purposes. These advantages have been sufficient to decide the committee on choosing water for the first division of the works; although subsequently, when additions will be made to the project, they consider it very possible that some other system, such as electricity, may be resorted to. On the whole, the conclusion they reached may be regarded with satisfaction. Electric transmission is scarcely as yet in so advanced a condition as to ensure that, on so large a scale, it would be applied from the first with security and success, and failure in so prominent an experiment would materially retard its future development. The probability—nay, the certainty—of this development is at the same time clearly recognised, and every encouragement thus given both to those who are engaged in its promotion and those who may be willing to put it to practical trial on a more moderate scale.

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 107).

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

#### HISTORY IN RELATION TO TELEGRAPHY.

Around the magnet. Faraday
Is sure that Volta's lightnings play,
But how to draw them from the wire?
He took a lesson from the heart—
'Tis when we meet—'tis when we part
Breaks forth the electric fire.

*Impromptu*, by Herbert Mayo, in *Blackwood's Magazine*.

In fact these experiments of Romagnosi and Schweigger are but modifications of one which dates back to the very earliest days in the history of electricity, and upon which, we have no doubt, Milner, in 1783, constructed the electrometer now known as Peltier's. In our second chapter we have said when speaking of Gilbert:—"In order to test the condition of the various substances experimented upon, Gilbert made use of a light needle of any metal, balanced, and turning freely on a pivot, like the magnetic needle, to the extremities of which he presented the bodies after excitation." Romagnosi and Schweigger have done no more than this—hardly as much, for Gilbert's contrivance was a valuable instrument of research, while those of the later philosophers were barren of results.

Other instances of this phenomenon, contributed by Robins and Kinnersley respectively, occur in the *Philosophical Transactions*, for 1746 and 1763; and a recent example, which is described in the *American Polytechnic Review*, for 1881, is considered so puzzling that "it is given for what it is worth" in the scientific paper in which we find it:—†

"An American surveyor, who had been taking some delicate bearings, was puzzled to find that the magnetic needle did not give the same bearing twice, and he observed that it never *quite* settled. This could not be explained as due to metallic articles in the dress, or pockets, of the observer; and an examination of the magnifying glass used in reading the needle was made. The magnifier was similar to those now universally used to read the verniers and needle-bearings of field instruments, having a black vulcanite frame, highly polished, and in this, it is stated, the whole cause of the trouble lay. It was found that this frame was peculiarly liable to become electrified, that the slightest friction, even the mere carrying in the pocket, was sufficient to charge it, and that, when thus electrified, if brought near the needle of a compass, it had almost the effect of a loadstone in drawing it from its true settling place. On discarding this magnifier and using an ordinary glass lens without a frame, no further trouble was found in the field work done with the compass. This must be taken for what it is worth."

As little value attaches to the observation of Mojon which we find, recorded by Aldini, and which seems to us but a repetition of Franklin's experiment (before mentioned), with this dif-

---

† An exactly similar case is recorded at page 280 Vol. XXI. of *The Quarterly Journal of Science and the Arts* (Royal Institution), for 1826.

Digitized by Google

ference that a voltaic battery was used instead of one of Leyden jars. Aldini says:—"The following experiment has been quite recently communicated to me by its author Mojon—

"Having placed horizontally sewing-needles, very fine, and two inches long, he put the two extremities in communication with the two poles of a battery of one hundred cups, and on withdrawing the needles, at the end of twenty days, he found them a little oxidised, but at the same time endowed with a very sensible magnetic polarity. This new property of galvanism has been verified by other observers, and lately by Romanesi, who has found that galvanism is able to deflect a magnetic needle."*

At page 120 of his "Manuel du Galvanisme" (Paris, 1805), Joseph Izarn describes Mojon's experiment, and appends an illustration, which shows most conclusively that it had no reference to electro-magnetism. His words are:—

"Apparatus for observing the action of galvanism on the polarity of a magnetised needle:—

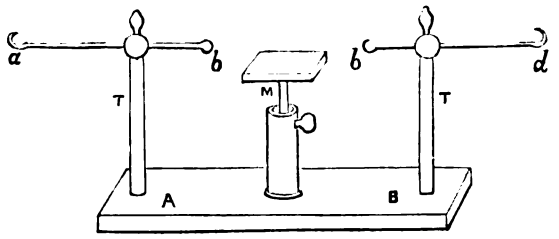

FIG. 2.—Mojon's Experiment, according to Izarn. Copied by kind permission of Mr. Latimer Clark.

"*Preparation.* Arrange the horizontal rods *a b*, *b d*, (Fig. 2) so that they may approach the magnetic bar shown between them, in place of the knobs *b b*, screw on little pincers which take hold of the magnetic bar, and attach one pole of a pile to *a*, and the other to *d*, thus completing the voltaic circuit through the length of the magnet.

"*Effects.* According to the observations of Romagnosi the magnet experiences a declination, and according to those of Mojon needles not previously magnetised acquire by this means a sort of magnetic polarity"†

In a paper read before the Royal Academy of Munich, in May, 1805, Ritter,‡ a Bavarian philosopher, advanced some curious speculations, which, although always quoted, as suggestive of electro-magnetism, are really as wide of the mark as the experiments of Romagnosi, Schweigger, and Mojon. We find them thus described in the *Philosophical Magazine*, for 1806 (XXIII., 51):—

"The pile with which M. Ritter commonly performs his experiments consists of 100 pairs of plates of metal, two inches in diameter; the pieces of zinc have a rim to prevent the liquid pressed out from flowing away, and the apparatus is insulated by several plates of glass.

"As he resides at present near Jena I have not had an opportunity of seeing experiments with his great battery of 2,000 pieces, or with his battery of 50 pieces, each thirty-six inches square, the action of which continues very perceptible for a fortnight. Neither have I seen his experiments with the new battery of his invention, consisting of a single metal, and which he calls *the charging pile*.§

"I have, however, seen him galvanise a louis d'or. He places it between two pieces of pasteboard thoroughly wetted, and keeps it six or eight minutes in the circuit of the pile. Thus it becomes charged, though not immediately in contact with the conducting wires. If applied to the recently bared crural nerves of a frog the usual contractions ensue. I put a louis d'or thus galvanised into my pocket, and Ritter told me, some minutes after, that I might discover it from the rest by trying them in succession upon the frog. I made the trial, and actually distinguished, among several others, one in which only the exciting quality was evident.

"The charge is retained in proportion to the time that the coin has been in the circuit of the pile. Thus, of three different coins, which Ritter charged in my presence, none lost its charge under five minutes.

"A metal thus retaining the galvanic charge, though touched by the hand and other metals, shows that this communication of galvanic virtue has more affinity with magnetism than with electricity, and assigns to the galvanic fluid an intermediate rank between the two.

"Ritter can, in the way I have just described, charge at once any number of pieces. It is only necessary that the two extreme pieces of the number communicate with the pile through the intervention of wet pasteboards. It is with metallic discs charged in this manner, and placed upon one another, with pieces of wet pasteboard alternately interposed, that he constructs his charging pile, which ought, in remembrance of its inventor, to be called the *Ritterian pile*. The construction of this pile shows that each metal galvanised in this way acquires polarity, as the needle does when touched with a magnet.

* * * * *

"After showing me his experiments on the different contractibility of various muscles, Ritter made me observe that the piece of gold galvanised by communication with the pile exerts at once the action of two metals, or of one voltaic couple, and that the face, which in the voltaic circuit was next the negative pole, became positive; and the face towards the positive pole, negative.

"Having discovered a way to galvanise metals, as iron is rendered magnetic, and having found that the galvanised metals always exhibit two poles as the magnetised needle does, Ritter suspended a galvanised gold needle on a pivot, and perceived that it had a certain dip and variation, or deflection, and that the angle of deviation was always the same in all his experiments. It differed, however, from that of the magnetic needle, and it was the positive pole that always dipped"* (C. Bernoulli, in *Van Mon's Journal*, Vol. 6).

Ritter also observed that a needle composed of silver and zinc arranged itself in the magnetic meridian, and was slightly attracted and repelled by the poles of a magnet; and, again, that a metallic wire through which a current had been passed took up of itself a N.E. and S.W. direction.

As the result of all these observations the Bavarian philosopher concluded that "electrical combinations, when not exhibiting their electric tension, were in a magnetic state; and that there existed a kind of electro-magnetic meridian depending on the electricity of the earth, and at right angles to the magnetic poles." (*Phil. Maga.* Vol. 58, p. 43). These speculations are, as we see, sufficiently obscure, and, like those that we have hitherto described, failed to throw any light on the relation so anxiously sought after.†

---

* "Essai Théorique et Expérimental sur le Galvanisme," Paris, 1804, Vol. I, p. 339.

† Mr Sabine appears to have studied Izarn, yet he writes thus, at page 23 of his "History and Progress of The Electric Telegraph," (2d Ed: London, 1869.):—"After explaining the way to prepare the apparatus, *which consists simply in putting a freely suspended magnet needle parallel and close to a straight metallic conductor* through which a galvanic current is circulating, he describes the effects in the following words" etc. The words that we have italicised are altogether misleading.

‡ "An ingenious and extraordinary man from whom much might have been expected, had nature permitted the continuance of his scrutiny into her secret operations. A premature death deprived the world of one whose constitutional singularity of opinion, ardency of research, and originality of invention, rendered him at once systematic in eccentricity, inexhaustible in discovery, and ingenious even in error." Donovan's "Essay on the Origin, Progress, and Present State of Galvanism," Dublin, 1816, p. 107.

Johann Wilhelm Ritter was born December 16, 1776, and died at Munich, January 23, 1810.

§ The charging pile, or, as we now call it, the secondary battery, was first described by Gautherot in 1801. See Izarn's "Manuel du Galvanisme," Paris, 1804, p. 250; also *Phil. Maga.*, for 1806, XXIV., 185.

* See further on this subject in *Phil. Maga.*, XXV., 368-9.

† It is curious to note that the English philosophers entirely neglected this study, being content to follow the brilliant lead of Sir Humphrey Davy in another branch of the science. Indeed, it seems to have been the general opinion in this country, as late as the year 1818, that there was nothing more to be discovered. Bostock, in his "Account of the History and Present state of Galvanism," published in London in that year, says:—"Although it may be somewhat hazardous to form predictions respecting the progress of science, I may remark that the impulse, which was given in the first instance by Galvani's original experiments, was revived by Volta's discovery of the pile, and was carried to the highest pitch by Sir H. Davy's application of it to chemical decomposition, seems to have, in a great measure, subsided. It may be conjectured that we have carried the power of the instrument to the utmost extent of which it admits; and it does not appear that we are at present in the way of making any important additions to our knowledge of its effects, or of obtaining any new light upon the theory of its action" (page 102).

Napoleon did not hold these views. In the First Consul's letter to the Minister, Chaptal, founding two prizes to encourage new researches in galvanism, he said:—"Galvanism, in my opinion, will lead to great discoveries."

(TO BE CONTINUED.)

## CABLES AND SURVEYS.

Telegraph cable expeditions in the present day do more than merely lay or repair cables, they supply a considerable amount of information which, though obtained primarily for their own work, adds considerably to our general knowledge of physical geography. Indeed, we may go further and say that, besides the discovery of submarine mountains and precipices in deep water, our cable engineers frequently supply here and there soundings were none existed, and corrections of previous soundings in shoal water which are useful in completing and correcting our Admiralty charts, and are consequently of direct use to navigation, whilst in other cases errors in the longitude of places have been corrected.

On the East Coast of Africa, and on the West Coast of South America particularly, an immense amount of fresh information has been gained on telegraph expeditions as regards the sea bottom near the shore, and in the numerous repairing expeditions in the Atlantic such rough ground and precipices have been found as to reduce the once far-famed "Atlantic Plateau" to a kind of excellent joke. In the earlier days of submarine telegraphy the Admiralty lent assistance occasionally in the shape of men-of-war to run lines of soundings, but now the various companies have to make their own surveys, and the process is reversed. Instead of the Admiralty supplying soundings to the various cable companies and contractors, the country, through the Admiralty, obtains the benefit of the surveys made by the telegraph cable ships, for all new soundings are courteously sent to the hydrographer, and as courteously acknowledged and published. In repairing expeditions the soundings taken are sometimes the result of many weeks' —sometimes months'—labour, over ground generally far from land, and the exact position where such soundings are required cannot be determined until the cable fails, so that the assistance of a survey by a Government surveying ship could not be asked for beforehand; indeed, the soundings in these cases are the result of the work itself. But when a new line is about to be laid it seems to us it would not be an unreasonable request if a preliminary survey of the route was asked for from Government. The expense incurred in delaying a telegraph cable ship, with its heavy compliment of highly-paid artificers, engineers, and electricians, during the time necessary to make a really careful survey of a route must be considerable, and might, we think, be fairly asked for from the Admiralty, and granted considering the advantage of submarine telegraphy to the country at large, and the moderate interest the shareholders receive in the shape of dividend.

The necessity of careful surveys of a cable route becomes from year to year more obvious. Such rough ground has been found in the Atlantic that it was almost impossible to grapple a cable upon it even when the cable was quite new; whilst the breakage of the cable when being paid out over the Seine bank between Madeira and Lisbon shows the danger run by laying cables over high submarine cliffs.

The account which we reprinted from *The Times* in our last issue of the soundings and other observations from the "Dacia" shows clearly, again, the extraordinary formations and dangers which exist but were previously unknown. In one place 66 fathoms were found within two miles of 414 fathoms, and three miles from this 810 fathoms. In another place a bank with about 550 fathoms is described as falling away precipitously from 550 to about 850 fathoms. "In one sounding on this ledge the sinker distinctly struck bottom in 550 fathoms, tumbled over, and continued to sink, struck in 620 fathoms, again tumbled over, and finally found a resting place in 850 fathoms." Here we have evidence of a cliff 300 fathoms in height, and the expense of sounding is well repaid by the information which permits of such a danger being avoided. This shows, too, that a mere line of soundings is not sufficient. When the soundings give suspicion of a bank the ground must be carefully examined, as it was in this case.

The danger of a bad route may be broadly divided into two, viz., precipices and rough bottom. The precipice would cause a cable, if laid too taut over it, to break sooner than at any other spot with a given decay, and may even break a quite new cable. The rough ground makes it difficult to repair when broken. The precipices may be discovered with an ordinary amount of careful survey with a wire and lead; the rough ground would require either very minute survey with the lead, or else some dredging with grapnels. Such surveys should certainly be made, but it is not following the ordinary procedure of engineering works to make this expense fall on the contractor. It is usual in ordinary engineering work, such as railways or canals, for the company's engineer to make surveys and then decide the route. In telegraph engineering it is the custom for the engineer to select his route from the information given on the

Digitized by Google

Admiralty charts, with the addition of such scant soundings as are taken by the contractors under his supervision from the loaded cable ships themselves. This, as we have pointed out, must be either expensive to the contractor, or can only be a flying survey, and the question arises whether, where the Admiralty will not or cannot spare a surveying ship to do the work, a small and inexpensive steamer might not with advantage be hired and employed for surveying the route by the company or administration whose property is about to be deposited for weal or woe at the bottom of the sea.

By some such arrangements the work would be performed more in accordance with other engineering practice. The engineers or advisers of the telegraph company would thus have fair means of obtaining reliable and accurate information of the ground to be traversed, and thus be able to select the very best route for the cable, whilst the contractor would be relieved from any delay to the cable ships, with their valuable cargo and expensive staff.

Of course, the whole Atlantic cannot be surveyed minutely to ascertain the very best route across, although it is evident that a best route must exist, and even our present experience gained from repairing expeditions teaches that some very bad spots exist which might be avoided by a little more minute survey than the single lines of soundings, at distances of from 30 to 60 miles apart, which have been the only guides hitherto. Our cable engineers and cable ship officers are becoming used to very nice work in nautical astronomy, and the tracks of cables and of dredge lines when repairing are now very accurately laid down. Indeed, there has grown up a staff of engineers who can now determine positions at sea, whether by angles to objects on shore or by observations of sun, moon, or stars, quite sufficient for executing the most accurate surveys of any seas. The introduction of the steel wire winding apparatus, and its constant improvement now permit of soundings in deep water being taken in about a sixth the time they took some twenty years ago, and thus a given amount of ground can be surveyed in much less time.

It was recently stated at the Institution of Civil Engineers by an eminent telegraph engineer, when speaking of the necessity of thorough inspection of telegraph material, that "many administrations object to the expense of thorough inspection, and the result is they are the recipients of the rejected material of those who do rigidly inspect." The remark was to engineers so obviously true that its enunciation caused quite a sensation of amusement. It cannot exactly be said that rejected cable routes will fall to those who do not inspect, but it is evident that a cable on a good route will last longer than one on a bad route, and that consequently the extensive repairing and perhaps loss of cable will more often fall to the company who object to the cost of preliminary inspection. We think there has been ample information within the last few years to show that there are dangers in deep water which can by proper examination be avoided. The question is one of cost of survey, as against cost of heavy repairs or a new cable. Large repairs and new cables benefit contractors; it is therefore for the companies laying new cables to seriously consider whether a more accurate and detailed survey would not be cheapest in the long run.

---

Western Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 14th December, 1883, were £2,146, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

## ROSS'S PRIMARY BATTERY.

Since Thursday, the 13th inst., Mr. O. C. D. Ross has been exhibiting, at 21, Austin Friars, E.C., an installation of electric lighting by his new primary battery. We visited these offices on the evening of the 18th for the purpose of inspecting the battery, and testing its work. Eight twenty-candle and twelve ten-candle Swan lamps were first switched on, the former in parallel and the latter in six branches of two each in series. The E.M.F. at the terminals and the current passing were then measured by accurately calibrated instruments, giving 49·5 volts and 15·9 amperes. The battery was then switched on to twenty 52-volt Woodhouse-Rawson lamps, but as the lamps did not appear up to candle-power, and the E.M.F. measured only 40·5 volts, six lamps were cut out, when the E.M.F. rose to 51·75 volts; the lamps giving full candle-power, and the current measuring 13·87 amperes. The Swan lamps in the first instance were, if anything, above normal incandescence. The battery, which consisted of 64 cells, was then disconnected from the circuit, and its initial E.M.F. was found to be 117 volts, while it gave 28·1 amperes on short circuit. Thus the total internal resistance was a little over 4 ohms, *i.e.*, 0·06 ohm per cell, while the E.M.F. was 1·82 volt per cell. The whole of the current was then turned on to a Clark and Bowman arc lamp, which worked very steadily and noiselessly. Small motors were also worked with fans attached, for ventilation, &c.

We next proceeded to inspect the battery itself in an adjoining shed about thirty yards distant. It was contained in four boxes, each about 1ft. square by 7ft. long, which were ordinarily kept closed. The one we saw open contained 13 double cells, the plates alone in each weighing about 10lb., the whole box weighing when charged 2cwt. Each cell consists of two carbon plates (formed by placing together carbon rods of $\frac{1}{2}$in. diam.), which are immersed in a solution of dilute hydrochloric acid, containing about a sixth part of Mr. Ross's solution, which he does not divulge, and learnedly dubs "Eureka." The zinc is contained in a solution simply of water and 3 per cent. of common salt. We were told that a quarter of the liquid was withdrawn and renewed on the 17th, after working for about 18 hours since charging. The mechanical arrangement for effecting the change of liquid is at once convenient and simple; a horizontal pipe connected by tubes to each cell is simply lowered, and the required amount tapped off, while all the cells are as easily filled in one operation by pouring into a groove extending the whole length of the box.

Regarding the consumption of zinc and constancy, Mr. F. Ormiston has tested "a portion" of a 60-cell battery with the following results:—

Experiment 1.—Current 14·32 amperes, which was the same after 6 hours continuous running.

Experiment 2.—Current 12·908 amperes, which, after 13 hours work, fell to 11·370, giving a mean of 12·430 amperes.

Zinc consumption in first case 10·75oz. per horse-power.
" " second " 12·75oz. " "
(We presume per hour.)

The bye-product, oxychloride of zinc, a grey powder, is, Mr. Ross claims, of value as a component of an insulating material, and therefore saleable. A sample of battery residue was analysed by Mr. James Forrest at the Chemical Laboratory, Greenwich, in which he obtained the following percentages:—Zinc 39·89, chlorine 15, oxygen 7·84, alkaline salts 0·21, moisture 25·16, ammonia, nitric acid, &c., 11·90.

With regard to cost, Mr. Ross claims that, omitting depreciation on the one hand and sale of bye-products on the other, which will vary in different cases, his battery will supply 1 horse-power of energy at 5d. per hour.

---

The Societe Generale des Telephones.—It is stated that this company now has 5,116 subscribers against 3,955 in last December. Of this number 4,794 are actually connected up, whilst of the 3,955 subscribers last year there were only 3,524 in connection.

## LES TÉLÉPHONES.

PAR A. L. TERNANT.

(CONTINUED FROM PAGE 113.)

The indicator is formed of two electro-magnets, the coils of which have a combined resistance of about 200 ohms. The indicator, and returns by point *c* and the hinder plate into the second line wire, whence it goes to the other pole of the subscriber's battery, thus completing the circuit. The central office replies to this call by means of the instruments, &c., shown in diagrammatic form in Fig. 9. They comprise a combined telephone connected to a commutator, C, of special form, designed by Mr. Brown, a calling key (Fig. 10), an induction coil, and two Leclanché batteries, the strongest of

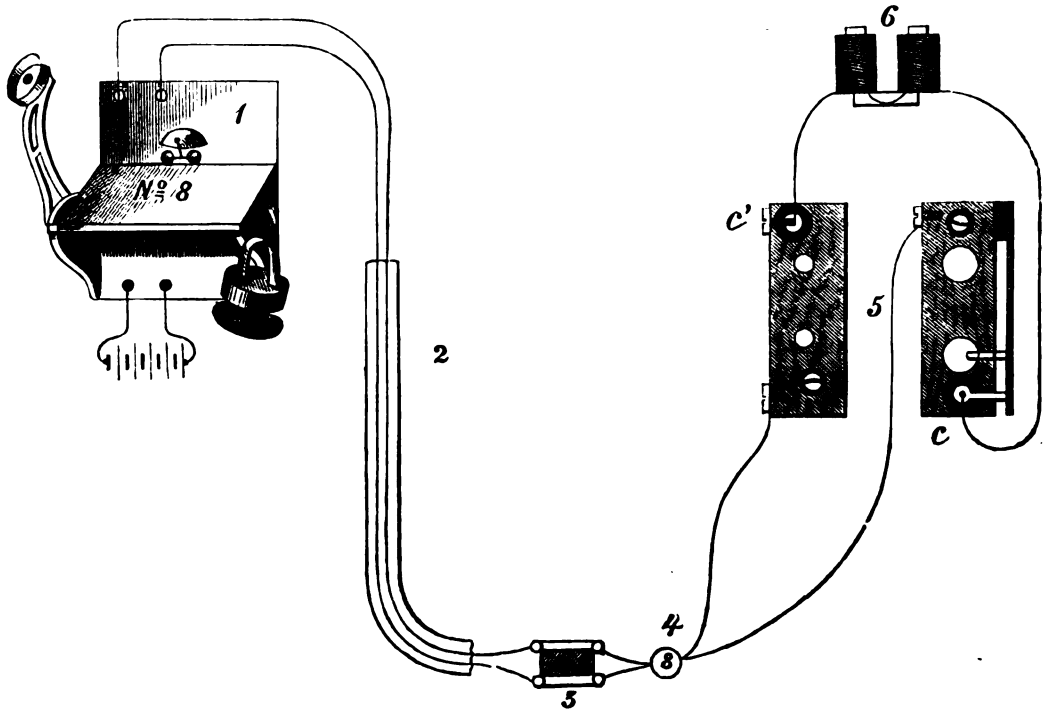

FIG. 8.—Circuit Arrangements: (1) Subscriber No. 8; (2) Cable of 14 Wires; (3) *Rosace* Commutator; (4) No. of Indicator and Wire; (5) Double Jackknife separated into two parts; (6) Indicator No. 8.

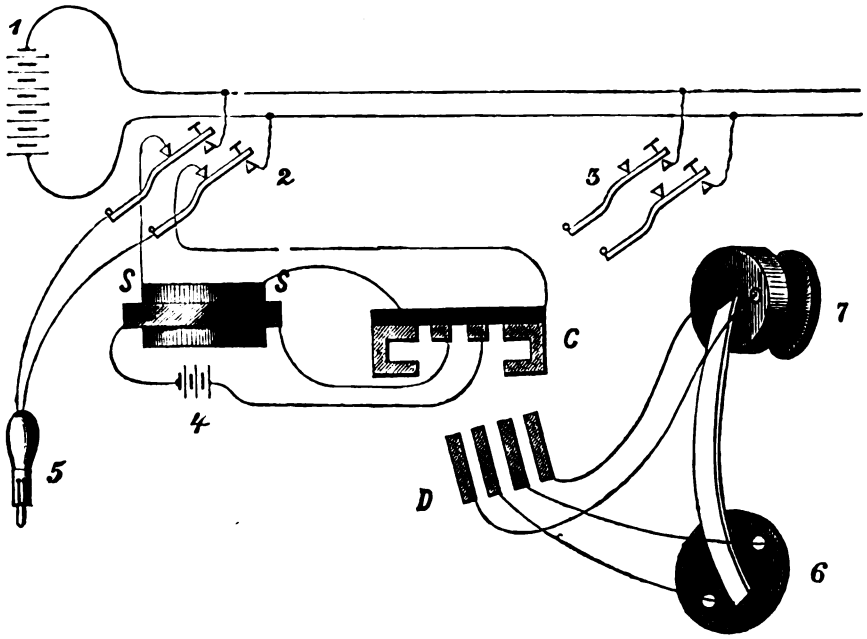

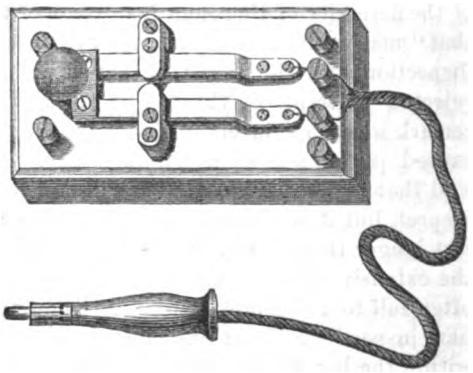

FIG. 10.—Call-Key with Plug and Flexible Cord.

FIG. 9.—Circuit Arrangements: (1) Call Battery of 20 Leclanché Cells; (2) First Call-Key; (3) Second Call-Key; (4) Battery in Microphone Circuit; (5) To Line; (6) Transmitter; (7) Telephone Receiver.

plug of the armature disengages a little cover which, by falling, discloses the subscriber's number. Fig. 8 shows the complete circuit, the jackknife being formed of two distinct parts. These parts are shown separately for greater clearness. It is seen that if the subscriber presses his bell push, the current from his battery goes to line, traverses the *rosace*, and arrives at the front plate of the jackknife, passes to the insulated point through the spring, traverses the which is used for calling purposes, and the other to generate induced currents in the coil.

These apparatus are not all to be seen in the office; they are fitted up out of sight. The flexible cord, connected to the calling key by two terminals, leads behind the pannelling of the room, and emerges again in front with the plug at the end of it. Fig. 11 gives a view of the actual connections to be seen in the central office and the indicators.

Digitized by Google

Each of the *employées* (the company preferentially employs young women) carries with her a combination of telephone and transmitter (Fig. 9). This must always be kept in perfect order. Let us suppose that No. 10 calls up. The operator at once inserts D (*vide* Fig. 9) in the commutator C. Fig. 12 gives details of D. By doing this she connects the transmitter with the small battery and the primary wire of the induction coil, whilst the receiver is put in connection on the one hand with the contacts of the key, which is connected with the double plug of the jackknives and consequently with the line, and on the other with the secondary circuit of the induction coil. By pushing the plug into the hole on the right hand side of the jackknife, the indicator is cut out of the circuit and communication with the subscriber is established. One or two calls made with the key warn the subscriber that he has been heard, and talking begins. The subscriber wishes to talk with No. 15. The operator accordingly takes the plug of the call-key out of No. 10's circuit, and goes through the above described operation with No. 15's wire, by introducing the plug into the left-hand hole of his jackknife, rings once or twice, and listens for the reply. When she gets it she informs No. 15 that No. 10 wishes to speak with him, and then, by means of a flexible cord both ends of which are furnished with a plug, connects Nos. 10 and 15 by introducing one of the plugs in the right hand hole of No. 10's jackknife, and the other plug in the left-hand hole of No. 15's jackknife. This done she can talk to both the subscribers, and put them in connection. She may then withdraw from the commutator C the piece making connection with her telephone, and betake herself to other duties.

(TO BE CONTINUED.)

## SOCIETY OF TELEGRAPH ENGINEERS AND ELECTRICIANS.

At the meeting of this society on Thursday, Dec. 13, the following report of the council was read by the secretary :—

"The council are enabled to report that the society continues to increase considerably in numbers.

The number of members of each class elected during the year has been as follows :—15 foreign members, 10 members, 123 associates, and 14 students.

Besides these, candidates have been approved for election next month.

By deaths and resignations our losses are as follow :—1 hon. member, 9 foreign members, 7 members, and 6 associates.

The losses by death have been, unfortunately, unusually severe—not, perhaps, in point of numbers, but in the large proportion of eminent men among those who have been taken from us.

We have to deplore the loss of our honorary member General Sir Edward Sabine, whose scientific labours, more especially in connection with terrestrial magnetism, are too well known to require enumeration; of Mr. C. V. Walker, past-president, one of the oldest associates of Messrs. Cooke and Wheatstone in their practical operations, and one of the

Digitized by Google

originators of the Electrical Society, of which this society is in some respects the successor; of Mr. Cromwell Fleetwood Varley, well known for his researches in every branch of electrical science, and for his numerous inventions in methods of its application; of Alfred Niaudet and L. Bréguet, distinguished foreign members; and within the last few weeks the sudden death of Sir William Siemens, twice our president, has inflicted a grievous loss not only upon this society but upon the whole of the scientific world.

The society continues to be indebted to the Institution of Civil Engineers for the great privilege of holding its meetings in the theatre of the institution.

Of the papers read during the year, of which a list is subjoined, several have proved of great interest, especially Professor Hughes's paper "On the Cause of Magnetism;" but the council regret that, among those eligible for competition for premiums, they are unable to discern sufficiently marked features to justify their awarding more than the society's prize of £10 to Mr. J. Munro, associate, for his paper on a "New Telephone Transmitter." They are unable to award either the Paris Exhibition premium or the Fahie premium for this year; but, nevertheless, desire to make honourable mention of the following papers, viz.:—"The Measurement of Electricity for Commercial Purposes," by Mr. J. N. Shoolbred, member, as a valuable communication on the subject; and "The Static Induction Telephone," by Mr. W. Moon, associate, for its originality.

The council trust that next year they may find themselves justified in awarding all the three premiums offered.

The incorporation of the society under the Companies Act, which was registered by the Board of Trade in May last, marks an epoch in the history of the society. The Articles of Association, which have taken the place of the former rules and regulations will be found to differ very slightly from the latter, beyond being more explicit and more conveniently classified under the various sections. They were most carefully revised by a committee of the council, who enjoyed the benefit of the legal knowledge of Mr. Fletcher Moulton, as one of its members, and the able services of your honorary solicitor, Mr. G. L. Bristow, for whose generous devotion of his time to the matter the society is deeply indebted.

The question of a standard wire gauge has again occupied the attention of the council.

Towards the close of last year the Board of Trade invited the opinion of the society on some modifications proposed to be made in the scale which they had previously submitted to the council, and which the latter had approved, accompanying the expression of their approval with a strong recommendation that the value in millimetres of the different sizes be given in a separate column.

The proposed modifications were in some respects considered objectionable to the council, and a deputation of the members had an interview with Mr. Chaney, the head of the Standards Department, when the matter was fully discussed, the result being that a standard scale has been adopted which meets with the approval of the council, and they are glad to see that their suggestion as to the metrical value being given has been adopted.

The council deem it their duty to refer to the services of the committee which they appointed to deal with this matter, and especially to the valuable co-operation of their past-president, Mr. Latimer Clark, whose labours in connection with the subject for many years past are well known, and have materially conduced to a satisfactory settlement of the question.

The society has again been called upon to use its influence, as a body representing electrical science and electrical industry, in connection with the recent Electrical Exhibition at Vienna.

When invited so to do by one of the vice-presidents of the commission, who specially visited London in the spring for that purpose, the council at once stated that, owing to many circumstances, it was not probable that any large number of exhibitors from this country would take part in it.

The result proved that they were right in this anticipation; for, notwithstanding the exertions of a committee appointed by your council to do all that was practicable in the matter, the British Commission, whom the Government appointed at a very late date, consisting of Lord Sudeley, Sir William Thomson, the late Sir William Siemens, and Sir Frederick Abel, found on their arrival at Vienna but a meagre collection of exhibits in the British section. At their urgent request the council succeeded in obtaining from some of the few members of the society who were accessible at that time of the year the loan of several further exhibits of scientific and historic interest, and these, which were exhibited in the name of the society, together with an important addition made to the collection already sent out by Her Majesty's Postmaster-General, rendered the British section more worthy of this country.

The society is much indebted to Herr Leonhardt, secretary of the Austrian Society of Engineers and Architects, and also secretary to the Exhibition Commission, who most kindly undertook the office of honorary representative of the society and agent for the British exhibitors.

It should be mentioned that the British Commissioners most cordially approved and endorsed all that had been done by the council previous to their appointment by the Government, and evinced their desire to co-operate with the society by appointing the society's secretary, Mr. F. H. Webb, as secretary to the commission in London, and Lieutenant Anstruther, R.E., an associate of this society, as secretary in Vienna.

The library of the society continues to receive numerous accessions, both by purchase and through the liberality of members and others, as will be seen by the librarian's report.

The society is much indebted to the gentlemen who represent it abroad as local honorary secretaries and treasurers, and whose kind services materially facilitate communication between our numerous members abroad and the secretary in London.

The finances of the society are in a satisfactory position, and have enabled the council, notwithstanding the expense connected with the incorporation of the society, to sanction an increase in the annual vote for the purchase of books and for binding, and also, as a tentative measure, an increase in the sum devoted to the preparation and translation of "Abstracts and Extracts" published in the society's *Journal*. A further amount has been invested on account of life compositions received during the current year."

The balloting for the election of officers for the ensuing year took place during the reading of the report, and in the course of the evening the result was announced.

### List of Officers for 1884.

President: Professor W. G. Adams, F.R.S.

Vice-Presidents: C. E. Spagnoletti, M.I.C.E.; Professor D. E. Hughes, F.R.S.; Sir Charles Bright, M.I.C.E.; Edward Graves.

Council (members remaining in office): William T. Ansell; Professor W. E. Ayrton, F.R.S.; E. B. Bright, T. Russell Crampton, M.I.C.E.; M. C. Forde, M.I.C.E.; Dr. J. H. Hopkinson, M.A., F.R.S.; Alexander Siemens, Augustus Stroh. New members: R. E. Crompton, William Crookes, F.R.S.; J. E. H. Gordon, B.A.; Lieut.-Colonel E. D. Malcolm, R.E., C.B.

Associate Members of Council: Captain G. W. Addison, R.E.; George Chatterton, M.A., Assoc. M.I.C.E.; Martin F. Roberts, F.C.S.

Hon. Treasurer: Edward Graves.

Hon. Secretary: Colonel Frank Bolton.

Auditors: J. Wagstaff Blundell (Wagstaff Blundell, Biggs, and Co., chartered accountants), 12, Delahay-street, Westminster, S.W.; Frederick C. Danvers, India Office, S.W.

Hon. Solicitors: Messrs. Wilson, Bristows, and Carpmael, 1, Copthall-buildings, E.C.

After the reading of the annual report, a description of a new instrument for measuring the strength of a magnetic

Digitized by Google

field was given by Mr. J. E. H. Gordon, who then read a paper "On a Method of Calculating the Total Horse-power Expended in a Network of Conductors (such, for instance, as a System of Street Mains)."

In all systems of electric lighting it is important to know what proportion of the electricity generated is utilised in the lamps, and what proportion is wasted in heating the conductor.

When we have a rule for determining this we can properly apportion the diameter of each conductor to the current it has to carry, and to the distance to which it has to carry it, so that on the one hand we may not, by making the conductor too small, expend too great a quantity of coal in forcing the current through it, nor, on the other hand, by making it too large, so increase our capital expenditure on copper that the interest on it is too large a proportion of the annual rental which we can charge for the electricity used in the lamps.

When the *same current* passes through two resistances, such, for instance, as a wire and the lamps fed by it, the horse-powers expended in the two resistances respectively are simply proportional to the resistances. For, if $r$ and $r'$ are the two resistances, the horse-powers expended in them by the *same current* (C) are respectively,

$$\text{H.-P.} = \frac{C^2 r}{746},$$

and

$$\text{H.-P.}' = \frac{C^2 r'}{746},$$

and their ratios are

$$\frac{\text{H.-P.}}{\text{H.-P.}'} = \frac{\frac{C^2 r}{746}}{\frac{C^2 r'}{746}} = \frac{r}{r'} \quad \ldots\ldots \quad (1)$$

When, as in arc-lighting, the lamps are all placed in series, the determination of the relative horse-powers is very simple, for the wire is of uniform section throughout, and its total resistance is its resistance per yard multiplied by its length in yards.

The resistance of each lamp is known, and the total lamp-resistance is the sum of these resistances.

*Example.*—Sixteen arc lamps, each of 2·1 ohms resistance, are placed on a circuit of 450 yards long, consisting of a wire having a resistance of ·006 ohm per yard. What proportion of the horse-power is used and wasted respectively?

The lamp-resistance $r = 16 \times 2{\cdot}1 = 33{\cdot}6$ ohms.

The wire-resistance $r' = 450 \times {\cdot}006 = 2{\cdot}7$ ohms.

The ratio

$$\frac{\text{H.-P.}'}{\text{H.-P.}} = \frac{r'}{r} = \frac{2{\cdot}7}{33{\cdot}6} = {\cdot}08,$$

or 8 per cent.

*Note.*—We must be careful not to confuse the ratio of horse-power wasted to horse-power used with the ratio of horse-power wasted to total horse-power.

The latter is the ratio of wasted horse-power to the sum of the wasted and used horse-powers, or

$$\frac{\text{H.-P.}'}{\text{H.-P.} + \text{H.-P.}'} \quad \ldots\ldots \quad (2)$$

This, in the case when the current is the same throughout the circuit, still depends only on the resistances and is given by the formula

$$\frac{\text{H.-P.}'}{\text{H.-P.} + \text{H.-P.}'} = \frac{r'}{r + r'} \quad \ldots\ldots \quad (3)$$

With a circuit as given in the previous example, the ratio of the horse-power wasted to the total horse-power would be

$$\frac{2{\cdot}7}{33{\cdot}6 + 2{\cdot}7} = {\cdot}074, \text{ or } 7{\cdot}4 \text{ per cent.}$$

With one group of incandescent lamps, either in quantity series, or of any combination of the two placed at the end of a pair of leads, as in Fig. 1, the problem of the determination of the relative horse-powers wasted and used is equally simple; for the wire being of uniform section, we know its resistance, and the resistance (R) of the group of lamps is given by the usual formula

$$\text{R} = \frac{r\,s}{q},$$

where $r$ is the resistance of one lamp, $s$ the number of lamps in series in each branch, and $q$ the number of branches arranged in quantity.

The current in every part of the leads being the same as the current in the group of lamps, the relative horse-powers are still proportional to the relative resistances.

We see in all these problems that the longer the conductor is, the thicker it must be; for if a given conductor wastes a certain horse-power, and we wish to double its length, *i.e.*, to put the lamps twice as far from the machine, without increasing the waste, we must also double its sectional area, so as to keep the resistance constant.

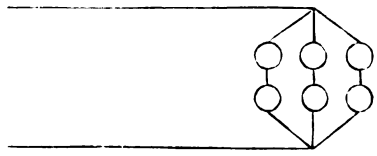

Fig. 1.

In practical incandescent lighting, however, the lamps are distributed at intervals along the pair of conductors, as in Fig. 2, and the problem at once becomes much more complex, because different parts of the conductors are carrying currents of different strengths, and the simple formula (1) is no longer applicable.

For in Fig. 2, if we consider the branches $L_1$ $L_2$, &c., as single lamps,

the portion $a$ of the conductor carries the current of 1 lamp.
" $b$ " " 2 lamps.
" $c$ " " 3 "
" $d$ " " 4 "

If we consider the conductors $+ d\,a$ and $- d\,a$ in Fig. 2 to be the wires laid along a side street, then the branches $L_1$ $L_2$, &c., will not be single lamps, but may each be considered to represent the whole group of lamps in one house; while, if we consider the conductors to be the mains in a principal street, the branches $L_1$ $L_2$, &c., may be considered as representing the sub-mains branching into the side streets.

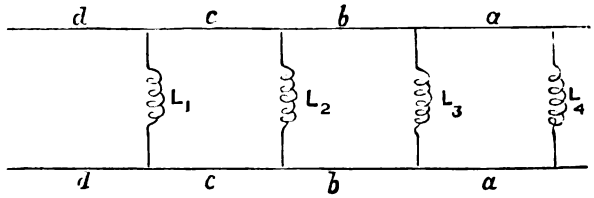

Fig. 2.

We see that $L_1$ $L_2$, &c., are not necessarily equal to one another.

In order to determine the relative horse-powers used and wasted in a system of town supply, I prefer to use the following method:—

We first mark out on a large-scale map of the district the number of lamps likely to be required in each block or house.

We then draw the street mains and branches radiating from the engine house to the houses to be lighted.

We then, starting from the furthest points on each branch, work up towards the engine house, marking on each branch and main the number of lamps it has to carry.

In a district so marked out we may use plain numbers to represent the number of lamps* in the block or house on

* The number of lamps need not be quite the total number erected, but should be the total number likely to be ordinarily in use. It is not necessary to provide copper to be always in position for lamps that are only lighted occasionally. In putting on extra lamps for short periods, care must, however, be taken that the heating limit is not approached.

Digitized by Google

which they are marked, and numbers surrounded by a circle for the number of lamps whose current carried by the wire near which they are written.

To avoid confusion, the + conductor only is shown, and when the h.-p. wasted in it has been obtained, the result must be doubled to obtain the total waste in the + and − conductors. Knowing the current used per lamp, we know the number of amperes which each wire has to carry.

We note that the "carrying" number in each branch is the sum of all the numbers beyond it, *i.e.*, on the side furthest from the dynamo in that branch.

*In order to secure the greatest economy of copper and of coals, the section of the conductor must be directly proportional to the current it has to carry*, i.e., *as we leave the dynamo, the section of conductor must diminish after each branch leaves it, in order that the same number of amperes per square inch may be carried by every part of the conductors throughout the system.*

This condition being given, then, for a given district mapped out, the amount of horse-power wasted in the conductors is simply proportional to the number of amperes per square inch which we use.

By the method we are about to explain it is easy to calculate the amount of horse-power wasted in the whole district for any given number of amperes per square inch.

In order to find the amperes per square inch corresponding to the particular percentage horse-power that we are prepared to waste, we must assume some number of amperes arbitrarily, and find the actual horse-power wasted, and then the required number of amperes will bear the same ratio to the required horse-power that the arbitrarily-assumed number does to the horse-power corresponding to it. . . . (4)

For example, suppose in a system where, say, 100 horse-power is being used in lamps, we are prepared to waste $12\frac{1}{2}$ horse-power, and that with an assumed current of 500 amperes per square inch we find, by the method of calculation which we are about to give, that we waste 16 horse-power, then the right number of amperes per square inch for us to use is

$$\frac{12\frac{1}{2}}{16} \times 500 = 390 \text{ amperes per square inch;}$$

and, if we have calculated the section of copper on the basis of 500 amperes per square inch, we must increase that section in the ratio of 16 to $12\frac{1}{2}$.

### Calculation of Horse-power Wasted.

We now come to the method of calculating the horse-power wasted in a system of conductors when a current of a certain number of amperes per square inch is flowing through it.

When there are the same number of amperes per square inch in a system, the *horse-power wasted in each cubic inch of copper is the same throughout the whole system or district.*

The resistance between the two faces of an inch cube of copper is ·0000007 (seven ten-millionths) of an ohm.

The horse-power (which we will call H.-P.) expended in a cubic inch of copper with a current of $\bar{C}$ amperes per square inch, is

$$\overline{\text{H.-P.}} = \frac{\bar{C}^2 \times \cdot 0000007}{746} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

With 500 amperes per square inch, the horse-power per cubic inch is

$$\overline{\text{H.-P.}} = \frac{500^2 \times \cdot 0000007}{746} = \cdot 000234 \quad . \quad . \quad . \quad (6)$$

When we know this constant, $\overline{\text{H.-P.}}$, and also the total number of cubic inches of copper in the district, we know the total horse-power wasted in the district.

To determine the number of cubic inches of copper in the district, we return to our map, on which the number of lamps in each branch is marked, and we calculate a constant for the area of copper per lamp corresponding to our assumed current of, say, 500 amperes per square inch.

For instance, if each lamp takes ·85 ampere, then for each lamp we must have

$$\frac{\cdot 85}{600} = \cdot 0017 \text{ square inch of copper.}$$

We then multiply the number of lamps on each section of the branch or main by this new constant, and we get the required area of this section, which we can mark on it on the map.

We next multiply the area of each section by its length in inches, and this gives us its volume in cubic inches.

Adding all the results thus obtained together, we get the total number of cubic inches of copper in the positive leads throughout the district.

Twice this result is the total amount in the + and − leads together.

Multiplying this result by $\overline{\text{H.-P.}}$, the horse-power constant (which, when C = 500, is equal to ·000234), we get the total horse-power wasted in the copper in the whole system.

If the horse-power wasted is more or less than the desired amount, we, as we said before, alter C proportionately to the desired change in the horse-power wasted.

We of course know the horse-power expended in the lamps, as we know the number of lamps and the horse-power expended in each.

If horse-power$_l$ is the total horse-power used in the lamps, and horse-power$_w$ the total horse-power wasted, then the percentage P.$_w$ of the whole horse-power expended which is wasted in the leads is

$$\text{P.}_w = \frac{100\,\text{H.-P.}_w}{\text{H.-P.} + \text{H.-P.}_w} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

As far as we have yet gone, we have assumed that all the lamps are alight whenever the current is flowing.

In practice this will not be the case, and we must note that if, the conductors remaining unchanged, we diminish the number of lamps on every branch in a certain *uniform* ratio, we shall diminish the wasted horse-power *in the square of that ratio.*

That is, if when 1,000 lamps are burning we are using 100 horse-power and wasting 10 horse-power, then, if we reduce the number of lamps to 500, we shall reduce the used horse-power in the ratio of $\frac{500}{1000}$, *i.e.*, to 50 horse-power, but we shall reduce the wasted horse-power in the ratio of $(\frac{500}{1000})^2$, or to $\frac{1}{4}$ of its former amount, namely, to $2\frac{1}{2}$ horse-power.

To put this in symbolical form, we may say that, with a given system of conductors, if

Horse-power$_m$ is the horse-power when M lamps are burning, and

Horse-power$_n$ " " N " "

then

$$\text{Horse-power}_n = \left(\frac{\text{N}}{\text{M}}\right)^2 \text{H.-P.}_m \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

This formula is, as we said above, only correct when the number of lamps diminishes uniformly over the whole system, *i.e.*, when an equal proportion of the lamps in every block is turned out simultaneously.

In districts containing the same class of houses, the condition is sufficiently nearly approximated to in practice to make the formula (8) a useful one in calculating probable waste. Assuming, then, this condition, we can, if we know the general average habits of the district as to the use of light, calculate the total relative quantities of coals which will be used in the engines in producing useful and wasted electricity respectively.

We will use the symbol H.P.H. for "horse-power-hour," *i.e.*, for a horse-power working for an hour Thus, 20 horse-power working for three hours would be equal to 60 H.P.H.

The coals used in an engine are practically proportional to the H.P.H., *i.e.*, to the horse-power developed multiplied by the hours during which the engine works. In order to determine the ratio of the coals used in producing wasted and useful electricity, we must take the H.P.H. used and wasted hour by hour throughout the night.

This will be best understood by an example.

Suppose that we have 1,000 lamps and a given system of

Digitized by Google

mains, such that, when all the lamps are on, we use 100 horse-power and waste 10 horse-power, and suppose that the number of lamps in use at the different parts of the night is as in the first two columns of the following table, then the H.P.H.'s used and wasted will be as in the fifth and sixth columns respectively, where the letters $l$ and $w$ stand for "used in lamps" and "wasted" respectively.

| Hours. | Lamps burning. | H.P.$_l$ | H.P.$_w$ | H.P.H.$_l$ | H.P.H.$_w$ |
|---|---|---|---|---|---|
| Before 5 p.m. | Very few | Inappreciable | Inappreciable | | |
| 5—6 ,, | 100 | 10 | ·1 | 10 | ·1 |
| 6—7 ,, | 500 | 50 | 2·5 | 50 | 2·5 |
| 7—10 ,, | 1,000 | 100 | 10·0 | 300 | 30·0 |
| 10—11 ,, | 800 | 80 | 6·4 | 80 | 6·4 |
| 11—12 ,, | 400 | 40 | 1·6 | 40 | 1·6 |
| 12—2 a.m. | 200 | 20 | ·4 | 40 | ·8 |
| After 2 ,, | Very few | Inappreciable | Inappreciable | | |
| | | | Total..... | 520 | 41·4 |

Thus, although the percentage horse-power wasted when all the lamps are on is from (7).

$$P._w = 100\frac{10}{100+10} = 9{\cdot}9 \text{ per cent.},$$

yet the percentage of coals wasted in the whole night is only

$$P._w = 100\frac{41{\cdot}4}{520+41{\cdot}4} = 7{\cdot}3 \text{ per cent.}$$

A discussion ensued in which Mr. Crompton advocated the multiplication of sources of supply as the most economical method; and also as the one most favourable to maintaining equal potential throughout the circuits and steadiness of the lights. In this view Professor Ayrton concurred, and quoted Professor Thomson's formula as to the size of the copper wire for given distances.

Mr. Thomas Blakesley said that he found very general misapprehension prevailed upon the economic law governing the size of electric conductors, and thought he could in a few words make the matter rather clearer.

The form of Thomson's law usually quoted, viz., that the area should be proportioned to the current was only true when the expense of installing the conductor varied as the cross section or weight per unit of length of the metallic conductor. This would be nearly true of a telegraph line, but when a conductor was insulated, there were many items of expense which did not vary as the area of the section. He had found that the expense of the insulation of a conductor varied nearly as the diameter of the metallic conductor, and in magnitude was often greater than the cost of the bare wire. This would be evident in some cases. The galvanising of a wire clearly included a sum varying as the diameter of the wire. Again, if a lathe had to be sheathed in a lead mantle of uniform thickness in such a way as to keep the capacity uniform, this lead would cost a sum varying as the diameter of the conductor.

There were items of expense which did not vary at all as the dimensions of the conductor, *e.g.*, the rent of a subway, within limits.

Of all such items the cost must be entirely deducted from the total cost before applying the law. And of those items which varied as the diameter, and which are very large, half the expense must be deducted.

Then on the remainder so obtained the interest should equal the cost of producing the energy absorbed.

He proceeded to explain this as follows:—

The expense will generally be, from the before going considerations of the form,

$$\text{Total expense } \gamma = \frac{C^2}{A} + a + b\,A^{\frac{1}{2}} + c\,A.$$

The first term being the expense arising from absorption, and the remaining three that of the conductor as explained above. This is the expression which is to be made a minimum.

Differentiating and equating to zero the differential co-efficient,

$$-\gamma\frac{C^2}{A^2} + \tfrac{1}{2}\frac{b}{A^{\frac{1}{2}}} + c = 0,$$

or

$$\gamma\frac{C^2}{A^2} = \tfrac{1}{2}b\frac{1}{A^{\frac{1}{2}}} + c.$$

From which equation it is clear that C can only be proportional to A when $b = 0$, *i.e.*, when there are no expenses varying as the diameter.

Multiplying by A all through,

$$\gamma\frac{C^2}{A} = \frac{b\,A^{\frac{1}{2}}}{2} + c\,A$$

$$= \left\{\text{Total expense of installation} - a - \frac{b}{2}\,A^{\frac{1}{2}}\right\},$$

which proves the rule quoted, that from the total expenses of installation, first the constant expenses, $a$, have to be deducted, and secondly, half the expenses varying as the diameter. The remainder then has to be equated to $\gamma\frac{C^2}{A}$ or the expense of absorption.

Professors Forster, Hughes, and Gisbert Kapp also spoke, when, after a reply from Mr. Gordon, and the usual vote of thanks, the meeting terminated.

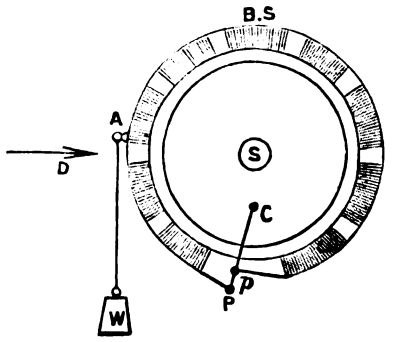
## CORRESPONDENCE.

### MECHANICAL DYNAMOMETERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the excellent series of articles which you are publishing on "Mechanical Dynamometers" by Mr. Gisbert Kapp, Figs. 11 and 12 in your issue of December 15 do not quite clearly represent the action of Appold's brake.

In the following figure the two ends of the brake strap



Appold's Brake.

B S are attached to the points P and $p$ of the differential or compensating lever or pendulum C $p$ P, the centre of suspension, C, of this lever being vertically below the centre of the brake pulley shaft S. If the friction be in excess of the normal, the point A to which the weights W are fixed will be lifted above the pointer D, and the lever C $p$ P will be pulled to the left as shown. Now, since the motion of P from centre C is greater than $p$ from the same centre, the brake strap will be slackened more from P than tightened at $p$, and A will descend to the level of the pointer D. If the friction be lessened below the normal by reducing W, the point A will fall below the pointer D, and the brake strap will be tightened more from P than slackened at $p$, thus bringing A up to the level of the pointer again.

This form of brake has a most important application in the

Digitized by Google

paying-out machinery on board telegraph cable ships. In such cases the compensating lever is fixed above the shaft, and the brake strap supported below by radial arms and springs, there being usually two brake straps and pulleys on the paying-out drum shaft.

The stress brought to bear on the cable is observed by the dynamometer, and regulated for the depth, speed of ship, and weight of cable by means of Appold's brake with the greatest ease and freedom from jerking, which could not be done by any ordinary brake.—Yours, &c.,

ANDREW JAMIESON.

College of Science and Arts, Glasgow, Dec. 17, 1883.

## ENDLESS CHAIN DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It is a pity that Dr. Ermacora did not adopt the same proportions as to the length of core, &c., as mentioned in my second letter.

If Dr. Ermacora will try the experiment again, with the iron core about one-third the length of the solenoid, he will most likely re-contradict by contradicting his own assertions.

I am not surprised at Dr. Ermacora failing with the experiment, because his iron core was 4 cents. longer than the solenoid. A core of this length, when in the middle of the solenoid, is practically of infinite length with regard to the magnetic field of the latter, and I think it is agreed between us that with a continuous core no movement can occur. Clearly, then, the length of core is of great importance.

Respecting Dr. Ermacora's trial with the Atwood machine, as the inertia of the balance weight and pulley would be likely to interfere with the speed on starting, I do not think it the best way of proving it.

So far from the experiment being in contradiction to the theory put forward by myself, I may say that as *a demonstrated fact* it was my starting point.

In considering the lines of force instead of the polarity of a solenoid, I agree with Dr. Ermacora that, "If the polarity of an iron rod put in the interior of a solenoid is opposite to that of the exterior one, this is only because, the lines of magnetic force being closed as rings, they must run outside the solenoid in the opposite direction to that they have in the interior." As it is impossible to detect *external* lines of force without polarity, I think it is best to study the matter from both stand points. It is difficult, however, to convey the impressions of individual thought by stereotyped phrases of science, more especially in dealing with such a subtle force as magnetism.

If it had not been for iron filings arranging themselves in lines in a magnetic field it is a question whether the hypothetical line of force would ever have been adopted. Just because molecules of iron arrange themselves in the direction of their length end to end, thereby forming lines in a magnetic field, does it follow that the magnetism which gives the molecules this particular property arranges itself in lines of force also? Granting the convenience of the hypothesis, there may be such a thing as over-doing it, and it is possible that by materialising that which is not material—inasmuch as magnetism can neither be weighed, felt, nor seen—we may be hindering the future discovery of what electricity and magnetism really is.

Dr. Ermacora's definition in italics as to the difference between permanent magnets and solenoids does not, so far as I can see, settle anything.

Dr. Ermacora's explanation of the currents produced in a closed magnetic ring is certainly ingenious, but is it true? Admitting that it is possible the current may be caused by lines of force cutting the coil by the simple act of shortening themselves when iron is caused to be present in the solenoid, how is it the current is induced in the coiled iron ring when contact is broken with a battery? In the latter case there are no external lines of force. Suppose a segment of the coiled ring to be occupied by a secondary wire of the same length as the solenoid in question, by breaking or reversing contact with the battery induced currents are set up in the secondary coil. In this case the lines of force must always be concentrated in the iron core. How, then, can *they* intersect the coils?

I have referred to the works by Du Moncel, Becquerel, and Jamin, quoted by Dr. Ermacora, and I find that the Page and Breton machine consists of a horseshoe permanent magnet coiled with wire. An armature or ordinary pole connector is caused to revolve before the poles of the magnet, and of course alternating currents are set up in the magnet coils.

The mode of generating currents proposed by me according to the principle described and illustrated at Fig. 4 in my last letter bears about the same resemblance to the Page and Breton machines as it does to the Bell telephone.—Yours, &c.,

E. L. VOICE.

London, Dec. 17, 1883.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I beg to thank Mr. Hitchcock for his offer regarding this. If he will communicate with me by post he will save you space, but either way will be acceptable.—Yours, &c.,

W. T. FARQUHAR.

Pitscandly, Forfar, N.B., Dec. 17, 1883.

[So far as our space is available, we hope our correspondents will continue to use it until the question of the defective dynamo is effectively settled. The matter is, we think, of interest to others besides Mr. Farquhar and Mr. Hitchcock, and we shall gladly insert any letters that may help to elucidate Mr. Farquhar's difficulty.]

## RECKENZAUN'S BRAKE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I remarked in *The Electrician* of the 8th inst. a very interesting article on dynamometers for measuring mechanical work. I was surprised to see what was called Reckenzaun's brake illustrated in sketches 6 and 7. This brake is nothing more than the well-known "balance dynamomé trique de Mr. Raffard."

The mistake is of no great consequence, but I beg leave to notice it in order that the same mistake may be avoided by any one wishing to reprint this interesting article.

I hope you will kindly reproduce this letter in your next number.—Yours, &c.,

VILLARD, Ingénieur des Arts and Manufactures.

12, Rue de la Sorbonne, Paris, December 13, 1883.

## WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In his letter under this heading in your last week's issue, Mr. Bengough states, by implication, that Mr. L. Clark has defined electricity to be "a substance . . . easily convertible into heat." I should be glad to know when and where such a definition was given by this distinguished authority.

It is obvious that if electricity could be converted into heat a definite mechanical equivalent could be assigned to it; and electricity would in that case be correctly classed amongst the modes of energy. But I may here repeat what I stated in the *Engineer* of July 31, 1868, when the question was fully discussed in that paper: "There exists no proof whatever that the conversion of electricity into mechanical work or heat is possible, and there is no experiment upon record, as far as I am aware, in which even a probability can be shown of such conversion having been effected."

On the other hand, I established beyond question, more than fifteen years ago, that heat may be generated, and mechanical work effected, *ad libitum*, by the passage to and

Digitized by Google

fro of a given quantity of electricity, without any conversion of the latter taking place.

The discussion of the present question may doubtless be of importance to a considerable proportion of the readers of *The Electrician*, provided your correspondents, whilst expressing their own views with precision, will appeal to experimental fact and verified laws, and avoid vague generalities and baseless speculation.—Yours, &c.,

DESMOND G. FITZGERALD.

## MAGNETO-ELECTRIC INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. J. De Vane asks for information on a point of considerable interest in relation to the theory of dynamo machines, and one which, so far as I have observed, has never once been intelligently referred to in the *quasi* explanations of the action of such machines put forward in the public lectures on the subject which were of such frequent occurrence a year or two ago. I say "intelligently" because some —I cannot say how many—of the lecturers actually referred the action of the Gramme machine to the inverse and direct currents in the armature coils which occur as the latter pass the poles of the field magnets. Mr. De Vane will, I think, readily perceive that these currents (of which one is necessarily in the same direction as the effective current traversing the coils from the positive to the negative collector on the median line, whilst the other is in the opposite direction) neutralise each other, and are wholly ineffective in the circuit whilst absorbing a certain proportion of the energy expended in driving the machine. The effective current in the coils is wholly due to the induced magnetism of the core. This current is *direct* as the coils approach the pole, and *inverse*, though in the same direction (since an inversion of the magnetic polarity occurs), as the coils recede from the pole. In order to understand clearly this action, to which the effective current is due, it must be borne in mind that the magnetism of the core, *considered as a ring*, is *nil* in that portion which is directly opposite the pole of the field magnet.

The complete physical theory of the Gramme machine (which is familiar to the members of my classes who have passed the elementary stage) is sufficiently simple, but cannot perhaps be very clearly elucidated without diagrams. I have probably, however, said sufficient to meet the question propounded by your correspondent, a question involving the most important imperfection in machines of the Gramme type.—Yours, &c. DESMOND G. FITZGERALD.

## THE SWAN LAMP.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: It may interest some of your readers to know that an incandescent lamp can be charged as a Leyden jar, from which a bright spark may be received if held to the hand. By holding the terminal of an incandescent lamp to the edge of a fast travelling belt, the electricity produced by the friction between the belt and the pulley may be stored in the lamp, and if a number of lamps be similarly held, with all the terminal joined, a much brighter spark will be obtained, proportional to the number of lamps so held—a verification of Franklin's discovery that the seat of charge is on the surface of the glass and not on the metallic coatings of a Leyden jar. —Yours, &c., J. B. DUNCAN.

16, Brandling-place, Newcastle-on-Tyne, Dec. 18, 1883.

## RESISTANCE OF THE CHROMATE CELL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you or one of your readers please inform me what would be the resistance of a bichromate cell having plates 1 decimetre (square), and their distance apart 1 centimetre?—Yours, &c., A. M. COCK.

12, Wellington-street, Torpoint,
Cornwall, Dec. 9, 1883.

## EASTERN ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

The second ordinary general meeting of this Company was held at the Terminus Hotel, Cannon-street, on the 14th inst., under the presidency of Mr. Ernest Noel, M.P.

The SECRETARY (Mr. Walter Jackson) read the notice convening the meeting, and the minutes of the last meeting.

The CHAIRMAN then said: I have to move that the report and balance-sheet be accepted, and in doing so I do not know that I need detain you very long, for I think the report itself explains the present position of the Company. Of course, I shall be very happy to answer any question if any shareholders think that what we have stated is not sufficiently explicit. There are just one or two matters in the report, however, to which I should like to refer. The first is the item of land and buildings in Bombay. They are put down at £8,300, and the information that we have received from India is that they are worth that amount. Whether they are so or not the home Board can have no opinion, but we are assured that that is the case. As regards the London expenses they stand at £5,948, which includes directors' fees; but I may say that the directors have received no fees (though they are put down here) for the last eighteen months nearly. That item, therefore, is really not nearly so large as it would appear. I may say that the directors' fees have been included because they were legally due. As to machinery, stores, &c., there is a sum of £1,627 under that head for London. Some may think that that is rather large, but the item is made up really of what we have paid for Swan lamps which were to be sent out. A considerable number have been and were to be sent out to Bombay. Then £200 was for the engines ordered by telegram for India, and £200 was also paid for lamp-posts for India. You will see that we had a capital of £80,000 to spend, and of that amount £76,000 has already been expended at Bombay under the authority of the Indian executive. There has been a sum of about £15,000 also spent in Malta, Egypt, and Penang. As to Egypt, we had advices which led us to suppose that there would have been a very profitable business there, and in all probability there might have been, but, as you are aware, the war broke out and destroyed any chances we might have had. With respect to Penang, a very small amount has been expended there, and the prospect even now of that place being taken up by some one seems very good. As regards Malta, the installation that was put up was successful; and if the Government had given us what we were led to expect—an amount of only 16 lamps—it would have been self-supporting, while if they had given us 24 lamps it would have returned us a fair percentage on the capital employed there. As to the progress of the Company—which, as this report shows, has been eminently unfortunate—I think we may say that the chief cause among a number of causes which has brought this Company to its present position was the determination of the Indian Government not to permit overhead cables. No underground system having yet been perfected that was suitable for a climate like India, the executive in India found almost insuperable difficulties in carrying out installations, and an installation which might afterwards have been successful failed owing to that cause. Some might say, as that was some time ago, why was there such an enlarged amount of business conducted there, after the Government had determined on that course? The answer is a very simple one, at least, as far as your Board is concerned. I hold in my hand abstracts of correspondence showing that we had no choice as to the course we were to pursue, inasmuch as we had, notwithstanding this difficulty, distinct orders from India as to what was required, and intimations that the orders which were being received were all likely to pay us from 10 to 20 per cent. per annum, and even more. The home Board therefore had simply no choice in the matter but to send out the goods that were ordered. When engines and dynamos were ordered by telegraph, it was quite evident that such orders were sent for some purpose that was clear in the minds of the Indian executive, and therefore the home Board could not refuse that which was for a purpose which we had already been assured would pay a good percentage. I do not know that there is any other point I should dwell upon except this, that I should very much like for my own part—and I think the shareholders would, but it is for them to decide upon—to have a committee of investigation appointed to look into the whole question of how this Company has been conducted. The directors have nothing to conceal. I can only say that I should be most happy to do all in my power to give such a committee every opportunity of investigating to the uttermost all that has been done, and I should rest perfectly content with the report that such a committee, formed of unbiased shareholders, would make. I still, looking back, believe we could have done nothing else than we have done. There have been certain initial mistakes. I think we made a great initial mistake when we gave so much for the patent, but that was at a time when the electric light was believed in very differently to what it is now. I think there were other initial mistakes. From the time, however, that we received advices from India as to the good work that was being done, the lighting contracts we had obtained, and the great prospects which lay before the Company—I say that the Board at home had simply no choice whatsoever, but to send out these orders that we received instructions for by telegraph and otherwise. I do not know of anything else that I have to say, and I will now move this resoluton:—"That the report and accounts to the 30th September, 1883, submitted to the meeting, be received and adopted." If that is passed I should be very happy to move or second a resolution appointing a committee of investigation to look into the whole of the correspondence and the entire way in which the business of the Company has been conducted. I should like it for the sake of the directors, and I should like it for the sake of the shareholders also. Of course, if the shareholders do not wish it we have no power of enforcing such a course, but I think it would be very advantageous to every one who is interested in the Company.

Mr. JAMES PENDER briefly seconded the motion.

Mr. H. D. BARKLEY inquired how it was that the Company did not ascertain first of all what the Indian Government was going to do as to overhead wires. It seemed to him that it would have been more business-like to have understood what the Government were going to do before the directors sent out such large consignments of goods to India. They had, he said, something like £56,000 worth of goods in Bombay which were

Digitized by Google

useless to them, as far as he could understand. It also appeared to him that if nothing could be done by the underground wire system it would be better to have this plant back and dispose of it.

The CHAIRMAN: We have no power.

A SHAREHOLDER said he should prefer not to wind up if there was any chance of the Company doing good.

Mr. BEDFORD said he was surprised that the chairman had not made some proposal as to the future of the Company. If any one had anything to say on that subject it was the Board, who had had from the shareholders £80,000, and had seen fit to spend £76,000 of that amount on machinery which appeared to be practically useless at the present time. He certainly endorsed the view of a previous speaker, that it was the duty of the Board to have found out whether the orders that came from India were *bonâ fide*, and whether the prospects were of such a nature as to justify the Board in dipping so far into the capital. He took exception to the remark of the chairman that the initial mistake had been made in paying such a large amount for the patent, as this Company, he said, really paid a very small sum comparedwith what was paid by others who followed them. Comparing the balance-sheet with those which had been issued by what he would call "the small fry"—the South Eastern and the Provincial companies, for instance—he could not help saying it was disgraceful.

A SHAREHOLDER: Do the directors still draw their fees?

The CHAIRMAN: If you had been here at the beginning you would have heard me state that the directors have received no fee for eighteen months, except the managing director. It was said that we ought to have found out what the Government were going to do. We could not do so except through our executive officers in India, and we had then to follow the advice of those who were on the spot. I do not wonder that some strong remarks have been made. I have lost too much in the Company myself not to understand the disappointment which must be felt. We were told that we ought to have looked into the orders we received to see if they were *bonâ fide*; but I am surprised at such a remark as that. Of course we looked into the matter, and took every care that we could. The chairman then read extracts from communications received from the Indian executive asking for goods, &c., and continuing, observed, There is one point which I forgot to mention, and it is very important. It was said that we ought to have seen what the Government were going to do as to overhead wires. I beg to say, as Major Strutt will tell you, that the Municipality of Bombay granted us special orders to run overhead wires before we embarked in this large outlay. The Supreme Government, however, afterwards interfered and prevented our doing so. As to the future of the Company, I do not know what proposal we are to make. The directors have been trying in every way they could think of to find out how possibly the business that has been established in India should be carried on. We have no means to do it ourselves. We have been striving to find out whether means could be found. It is quite evident that the shareholders would not give us more money. If I thought they would I would ask them to do so, but I did not propose that course, as I did not anticipate that it would be agreed to. We have been looking about to see what could be done, but in the present state of the electric light I do not see any body of persons ready to take it up. You must remember that since we took it up there has been a great change in the opinion of the public as to electric lighting. Some time ago there was great belief in it, and I myself have still great belief in it. I believe that eventually electric lighting is sure to be established, though the difficulties are very great and they have not been overcome yet by the scientific men who are studying the question. When a proper underground system has been discovered that can carry on a good installation, I believe you will have most certainly satisfactory electric lighting, but until that is done I do not know how we are to meet the difficulty. We cannot be pioneers in that sort of thing. We have neither the means nor the opportunity. We cannot invent what others have not invented. Meanwhile, all I can say is, if the shareholders like to wind up, that is one way of getting over the difficulty. If, on the contrary, they like to stay on as long as possible, in the hope that we may find some one who will undertake the work which we have begun, and well begun, in India, that might be done. I must make this statement—that I believe there is no electric light company in the world that has done so much and such good lighting as ourselves, and that there are none who have worked under such great difficulties. I am not going to say that there were not faults and mistakes—in a new enterprise like this there may have been plenty, but I repeat that I believe no electric light company in the world has done so much and such good lighting as this Company, and had it not been for the action of the Government in India, I think we should not have been in our present position. Almost all the failures of the lighting in Bombay arose from the action of the Government, and prevented the formation of the company that was on the point of being formed. As to that matter, I may state that we had a telegram informing us that everything was agreed to, and I thought so. If the company had been formed we should have been relieved of all our difficulties in Bombay, and have had fresh capital to make a start at Calcutta, with every chance of success. What caused the prevention of that company being formed I cannot say precisely, but I have no doubt that it was owing to our underground system and its failing. In further reply he stated: The underground system at present in India has been a failure. It is a very different thing to lay a small amount of underground electric wire and to lay forty or fifty miles, and it is also another thing to lay it in a country like this and in a country like India, where there is enormous heat in the ground—to a large extent melting ordinary cable—and, in addition, the tremendous monsoon rains.

A SHAREHOLDER inquired on what ground the Supreme Government upset the authority given to the Company by the Municipality of Bombay to lay the cables overhead.

The CHAIRMAN: As I understand it was the belief they had of the extraordinary danger of overhead wires. I think the ignorance displayed in this matter by the Supreme Government was something extraordinary. They published a long statement of their reasons, two-thirds of which, I think, were known to be absurd by every electrician in this country. Do not let me be misunderstood in this matter. I think an underground system is vastly better than overhead, though I do not think there was the danger or the difficulty in India that there would be in this country. Still, no doubt, an underground system would be far better than overhead. In further reply he stated there had been nothing paid to the Indian and Oriental Company for accumulators, because till quite lately from one cause or other—chiefly this very question of underground wires—they did not work. He then put the motion, which was carried.

On the motion of Mr. PAYTON, the auditors, Messrs. Deloitte, Dever, Griffiths, and Co. were afterwards re-elected.

The CHAIRMAN: I think the shareholders would like to hear Major Strutt give some account of his experience in India, because, no doubt, the larger part of the expenditure—something like four-fifths of it, was under his orders in Bombay.

The MANAGING DIRECTOR (Major C. H. Strutt) then said: When I went out to India two years ago it was under the impression that we were to form small local companies there, and not to carry out any great works of our own, but on my arrival there I found that it was impossible to form any company unless we showed what we could do, and what our patents were worth. It was with this object that I started operations in Bombay, and obtained the first contract for lighting the markets. We had great difficulty in getting electricians, but after several attempts we gave a good installation. We got contracts with the municipality, which gave us £600 a year. We then undertook the lighting of Prince's Dock, which was a large affair, and it was entirely by that system of lighting that the troops were enabled to be despatched as they were. The issue of the orders of the Supreme Government as to overhead wires completely paralysed all our operations. A shareholder asked why we did not make inquiries beforehand whether the Government were going to stop these overhead lines. Considering that the telegraph and telephone lines were all overhead we had no reason to suppose that we should be interfered with by any one. We looked on the Bombay municipality as supreme in their own district, as they did themselves. We were just as much astonished as the municipality were at these orders from the Supreme Government. The Bombay municipality supported me. I have entered into a long correspondence with the Supreme Government on the subject, and I believe the home Board tried to get this restriction cancelled, but without effect. Our business operations in Bombay extended so rapidly that I saw it was necessary to erect buildings and purchase land and carry out the works we had in hand. We took contracts for erecting 100 arc lights, which were to bring us in a revenue of £4,000 a year. Our orders for incandescent lighting were unlimited—in fact, they are now if we could carry them out. If we could carry out orders for incandescent lighting in Bombay they would exceed £20,000 a year. The home Board sent me out very good electricians, who introduced a very good underground system, and we laid our cable to carry out the orders of the Government, and we thought with the greatest success. The cable would not carry the high tension current with which we worked during the heavy rains in Bombay from June to September. The test boxes got full of water, and the installation failed. The two cities of Broach and Surat were lighted with great success, but a heavy flood arose in Surat, and the whole city was under water for some time. These separate installations were put up and covered expenses, and we anticipated that the municipality would eventually buy them from us, and I believe they would if we can carry on our work. We waited very anxiously for accumulators to be sent out for Bombay, and after waiting for some months they arrived. Our own electricians were not experienced in them. The first lot were damaged in being sent out, and we failed with them, but eventually a good installation was carried out. During all that time, however, with the delays, and the orders of the Government, our finances ran very short. The chairman made some remarks about a committee of investigation. I am perfectly willing to bear the responsibility of ordering the machinery, and of my own operations out there. I think we should not forgo what the chairman has suggested—that an independent committee should be appointed to investigate the affairs of the Company, and to go thoroughly into the whole matter—the past, present, and future of the Company. As far as I am concerned, I am perfectly satisfied that the Company can be made to pay. We have some very excellent contracts in Bombay now, which pay their own expenses, and by a reduction of the staff and careful economy in carrying on the work, with the assistance of the shareholders, there is no doubt that the Company can be restored. I do not take the gloomy view of the affairs that possibly some of the other directors do. I am ready to give you every assistance. I feel perfectly certain that among ourselves we can pull the Company through its difficulties. The lighting in India is unlimited. The Gas Company at Bombay have spent £250,000 on their works. They get from the municipality about £22,000 per annum for street lighting, and their private lighting is about £25,000 per annum, and out of this revenue they pay only 7 per cent. We have a license from the Bombay municipality, which I may say is almost a monopoly. We have a ten years' license with them to open the streets to run our underground lines, and at a nominal rental. We pay £10 a year per mile of lines run underground after the second year of working. They repair the road after us, and assist us in every way. When the gas contract expires, in about three or four years, I have no doubt that we shall have the entire lighting of the streets of Bombay with 500 or 600 lamps, which will bring us a very handsome revenue, that is if we can hold on. I feel perfectly certain that no license will be given by the municipality to any other company as long as we can carry on our work, so we may look on it as a monopoly. The price of gas in Bombay is 10s. per 1,000 cubic feet, and there is no difficulty whatever in competing with the gas company if we can carry out the orders we have in hand. I feel perfectly certain that the whole of our business rests on incandescent lighting. Whether we are able to carry out the orders I cannot say, but as far as orders go they are unlimited. The Indian and Oriental Company have acquired a new accumulator, which I believe will help us very materially, but if not we must work direct from machines, as Edison does. There is a very large business to be done with the native States, but the order of the Supreme Government has created such a scare throughout the country as to the danger of electric lighting that for a short period there was a lull in the demand, and all the orders for which I was negotiating when I sent those telegrams were withdrawn. That was the consequence of this ridiculous order from the Supreme Government. In conclusion, I move that a committee be appointed to inquire into the affairs of the Company, and that if their report is satisfactory they should bring the same before the shareholders, with certain proposals as to the future management of the Company. I feel that we shall certainly have to issue debentures, but I believe the majority of the large shareholders would have no objection to take them up at 7 per cent. on mortgage of their property. I consider the buildings and land in India are quite of the value we gave for them, and our plant and machinery are quite sufficient

Digitized by Google

to carry on our business. We might do an entirely selling business, undertaking small contracts to sell outright, and, if possible, form small subsidiary companies for taking up our patents. In reply to a question he added: The work in Bombay is being carried on by an agent.

The CHAIRMAN: I think the lighting must be stopped at the present moment, but we have not had telegraphic advices in the last week.

The MANAGING DIRECTOR: I beg to differ from the chairman in that. In reply to other questions he said: We are not quite paying our expenses. We should be if we had no debts to pay. We telegraphed to our agent in Bombay to cease work unless he could obtain money to go on. We have had a reply from him that he was raising about 150,000 rupees, which would enable him to pay off our liabilities and give him capital to go on with. I believe that the underground system would answer, but not with our present cable, which was sent out entirely for overhead lines. I believe myself that an underground line is available, but not for permanent work. Still, it would enable us to carry on our work for two or three years, which would be all we want. I feel sure that the Company may be pulled through with the assistance of our shareholders. I quite agree with the chairman that it is much better to have underground lines in the streets. I do not believe there will be the same difficulty as before in running the wires overhead for up-country lettings.

The CHAIRMAN, in further reply, stated that the directors had been doing their best to carry on the operations of the Company, and the directors would render every assistance they could, and would not stand in the way of others. He would not think of retiring until they had exhausted every resource, and saw that there was no way of going on. They had heard Major Strutt, who he hoped was right in his views.

The MANAGING DIRECTOR, in answer to other questions, said that if they sold machines at a reduced price, which he believed they ought to do, they could make a profit on the sale of their carbons, as the Jablochkoff Company did with their candles. They had no competitor in Bombay, and none in India, except the Jablochkoff Company. By steadily going on he believed they would yet be able to form a company in Bombay. There was no doubt that a cable could be made to carry the current underground. He regretted that Mr. Latimer Clark (one of the directors) was not present, as he believed that that gentleman had made such a cable.

Mr. BALL: You have only £370 left. How can you carry on?

The CHAIRMAN: That is a very difficult question, and it is the point we have to try and solve.

The motion was carried, but the proposal for the appointment of a committee was not taken up by the shareholders, and consequently fell through.

The meeting closed with a vote of thanks to the chairman and directors.

## METROPOLITAN BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

The ordinary general meeting of the shareholders of this Company was held on the 17th inst. at the Cannon-street Hotel, under the presidency of General Sir Michael Kennedy, R.E., K.C.S.I.

The notice convening the meeting having been read,

The CHAIRMAN, in moving the adoption of the report and accounts, referred at some length to the past proceedings of the Company, and to the difficulties which had beset them. The demands on them from the outset for incandescent lighting had been very great, but they had not had the power to do the work; and their original agreement with the Anglo-American Brush Corporation would have been fatal to them, as it bound them to the use of the patents of that company. They had, therefore, entered into a new agreement with that company.

The SOLICITOR (Mr. Webb) having read the heads of the agreement,

The CHAIRMAN, continuing, stated that under the new arrangement they had powers to use any system they pleased, and the Anglo-American Company would have to pay them a liberal royalty on any business which they did in the Company's district. There were other advantages which the Company had secured by the new agreement. Referring to matters in connection with the formation of the Company, he stated that a case had been prepared by Messrs. Linklaters, and had been submitted to Mr. Romer, Q.C. The directors had also had a long conference with that eminent counsel, whose opinion was that the company had no claim against the Company or any person referred to in the case. The opinion of the Solicitor-General was subsequently taken on precisely the same case, and his opinion was that their only remedy would be against the City and Suburban Company, which had been dissolved. After having taken these opinions the directors decided to leave law alone and to push on with the business of the Company. They had obtained twenty-three provisional orders, but they had deferred proceeding with them from various circumstances. They were going, however, to take up the lighting of the Holborn district, where a house to house canvass had been taken, with the result that they had obtained orders for 3,000 incandescent and 50 arc lamps. On the basis of the present price of gas these orders would give them 8½ per cent. on the expenditure, which was estimated at £14,400. As, however, they supplied a better article than gas they should obtain a better price, and at 25 per cent. above the price of gas they would get a return of over 16 per cent., which would increase as the number of the lamps increased. This district would be a test experiment, and if it succeeded they would proceed with the other orders. The deposits, however, must be paid before the 11th February, or the orders they had obtained might be lost. In the circumstances in which they were placed they had approached the Board of Trade, stating their position frankly. They had asked whether, pending their going on with the Holborn order, a reasonable extension of time would be granted to them with regard to the other orders. The reply was to the effect that a favourable response to their application might be looked for if the position of the Company remained substantially as it was at present. The Board of Trade acted on just and reasonable principles, and they felt that it would be injurious to the best interests of electric lighting enterprise if the work were carried out hastily. In the next few months they might receive proposals as to their other orders which would prevent the necessity of their finding further capital; but the importance of proceeding with the Holborn order was manifest. They had also entered into an agreement with the Hammond Company for the practical carrying out of their work.

The SOLICITOR having read the heads of this agreement,

The CHAIRMAN said he thought it was a favourable arrangement for the Company. They were not bound to that company's system by the agreement, while as to the advantages they secured, they would have the use of the Hammond Company's factories and the services of a skilled and trained staff, without having to incur the expense of creating and maintaining such a body. In addition, they would share equally with the Hammond Company in all outside contracts, and incur no risk in connection with these contracts, and at the same time their own work would be done without risk at a small contractor's profit. They would have noticed that either party was entitled to withdraw from the agreement, unless further capital were called up by this Company within a certain period; but the directors would not make a call unless they saw their way to employ the money profitably. Under the agreement all disputes between the two companies would cease. They regretted the action which the late manager, Mr. Pollock, had taken, and the directors were unanimous in condemning that gentleman's attempt to force a new policy on them. Mr. Pollock was a zealous officer, but his zeal was untempered with discretion. Mr. Pollock had sent out a circular to the shareholders, but it would be wasting their time to analyse it. It was not, however, to be supposed, because Mr. Pollock's statements were unanswered, that they were unanswerable. A number of shareholders had also issued a circular inviting proxies to be sent to them to enable them to oppose the policy of the directors. The Board had communicated with those gentlemen, and he was glad to say that their object was not destructive, but that, on the contrary, they were as anxious as were the directors for the success of the Company. That being so, the Board would be glad to meet these gentlemen in any way that they possibly could, and accept any reasonable proposal they might make. The directors had nothing to conceal, and were ready to give every information they could, but they would not agree to any measure that would have the effect of stopping or retarding the acceptance of the report that day, and they deprecated any course being taken which would be likely to injure the prestige of the Company at a time when they required all their credit and strength to deal with the difficult matters before them. He concluded by moving the resolution.

Mr. J. H. BORRER, in seconding the motion, said he did not speak as a director holding a few shares, with a reputation for good judgment, but rather as a very large shareholder, his shares having been acquired at a high price. He had joined the Board in order to have a voice in the management of affairs which so largely concerned him, but he had become a director at great personal inconvenience. His interests he wished them to see were identical with those of the general body of the shareholders. He only joined the Board last August. If his co-directors had not agreed to accept or to propose a course which in view of the mystery and strange dealings surrounding so many electrical companies, and in view of the large sums of money expended by this Company, with hitherto such bad results, he thought the shareholders were justified in desiring, he could not have felt himself sufficiently at one with his colleagues to occupy the position in which he stood that day. He was convinced that the shareholders who were associated with Mr. Andrea and Mr. De Roubaix had no desire to upset the Company, and that they desired to see the best use made of the opportunities before them. He also thought it entirely reasonable that they should want to know a great deal more about the affairs of the Company, and everything bearing upon them, than they did at present, and to exercise some influence upon its future management. To meet these wishes the directors were perfectly willing that a small committee of shareholders should be appointed to whom free access should be given to every record and document, that the committee should also thoroughly examine the accounts from the commencement to the 1st inst., that they should embody their conclusions in a report, and submit it to the Board, and if not satisfied with the attention given to their recommendations that they should send in a requisition for a general meeting. After explaining the various circumstances which had led to the delay in the issue of the report, and the holding of the meeting—the obtaining of the provisional orders and estimates in connection with them, the negotiations as to the opinions referred to in paragraph 9, and the agreement with the Anglo-American Brush Corporation—Mr. Borrer stated that the policy which it was now proposed to follow—as set out in paragraphs 5, 6, 7, 8, and 9—he, as a large shareholder, believed to be sound and hopeful. The claims which they might have preferred against the Anglo-American Corporation were most difficult, and in many respects impossible to establish, and by giving up these unsubstantial things the Company had obtained a royalty on all machines used by the Brush Corporation in the metropolis (which was likely to come to something very substantial), and the settlement on their own terms of an account for £5,000 against the Company, of which they only thought they ought to pay £1,000. By giving the Brush Corporation liberty to work in a way which would bring this Company a permanent income without expenditure of capital they themselves obtained the freedom without which they could do scarcely anything themselves. He took it for granted that the proposal to commence with one small district first, and not to rush into several before they had much experience, must commend itself to all of them. Holborn was a good district to start with, and the estimates in connection with the works would bear examination. The agreement with the Hammond Company seemed to him a good one. He thought the Board had, since he joined them last August, met the somewhat difficult circumstances they had had to face in the best way possible. Having expressed a hope that the offer of a committee, as suggested by the chairman, would be accepted, he alluded to the circular which had been issued by Mr. Pollock and the course taken by that gentleman. He certainly thought that Mr. Pollock's judgment had been at fault, but he had been most pleased to hear from him that he had obtained a new appointment fully as good as the old one, and he was sure that Mr. Pollock's new employers would have a zealous and energetic officer.

A protracted discussion followed, in the course of which

Mr. CHARLES BELL moved an amendment not adopting the report, appointing a committee of investigation, &c. He believed that they would be able to make some one "disgorge" some of the £235,000 which it appeared had been paid for the patents.

Mr. POOLE seconded the amendment. He said he represented an original shareholder, who was resident at Antwerp, and who held 2,000

Digitized by Google

shares, upon which he had paid £3 per share. Referring to the accounts on the asset side there was put down as an asset £235,000 paid for the concession. He did not say one word as to the amount paid to the Brush Company or to the Hammond Company. Those might or might not be correct values for what was purchased; but, according to the prospectus, the whole amount paid to those two companies consisted of £170,000, so that there was a slight sum of £65.000 which had dropped in between on the way. He asked what value this Company got for the £65,000? He also asked for what purposes the City and Suburban Company was floated and incorporated. He contended that it was in order to enable promoters to plunder the public. It was a dodge in order to avoid certain provisions of the law courts, which placed promoters in the position of trustees for the company they floated. Messrs. Walter Webb and Co. floated the City and Suburban on the 13th May, and on the 15th this Company was brought into the world. On the 10th July, 1882, liquidators of the City and Suburban Company were appointed, and he did not think it was too much to ask whether any of the money went in a certain direction?

Mr. WEBB: Do I understand you to suggest that any part of that money went into my pocket?

Mr. POOLE would be very glad if Mr. Webb would tell them the whole of his connection with this Company. He thought that the shareholders were justified in asking for an investigation.

Mr. BROWN said the cases that had been submitted to counsel had been prepared with the greatest care, and every detail had been given them, in addition to which he had had many long interviews with the eminent gentlemen whose opinions had been cited. He acknowledged that he was of a different opinion, but contended that the directors were right in abiding by the advice of such gentlemen as Mr. Romer and the Solicitor-General. Everything which in the least degree bore on the liability of promoters was stated in the case.

Mr. PEEBLES said that while he was a member of the Board he constantly insisted that an investigation should take place, and when he retieed in consequence of ill-health he wrote to say that he would remain if his request were acceded to.

The CHAIRMAN said he did not remember that there was anything in Mr. Peebles's letter of resignation to that effect.

Mr. PEEBLES requested to have the letter read, but it was not forthcoming.

Mr. DIGBY SEYMOUR thought the shareholders would consult their own interests if they considered the suggestion to appoint a committee of conference and not one of investigation. A hostile committee would reflect on Mr. Brown and Mr. Webb. They would jeopardise the interests of the Company if they showed a want of confidence in the directors. He believed the policy of the Board was one of caution, limiting their operations for the present to Holborn, and endeavouring to avoid a call. He regarded the value of their provisional orders as worth at least £10,000 a piece, and he believed, therefore, that the prospects of this Company were very encouraging.

Mr. ROBERTS thought that the committee should consist of the largest original shareholders.

Mr. POLLOCK denied that he had persisted in a course of litigation, but said that he had always contended that investigation was necessary. He had never been permitted to see the legal opinions which had been given, while they had been shown to Mr. Webb, whom they most concerned, and from whom they should have been kept. With regard to his having attended a private meeting, he contended he did that in the interests of the shareholders.

Mr. WALTER WEBB said that he should be very sorry to occupy any position in the City of London after twenty-five years in his profession if he were ashamed to meet any body of shareholders, and to give them in the fullest and most complete language all the circumstances of any transaction in which he had been engaged. It was stated in the prospectus that the solicitors of this Company were also the solicitors of the vendor company. The vendor company was, as they had been told, the City and Suburban Company. It had been asked why that company had been formed. It was this very special and necessary reason—25,000 sovereigns had to be deposited with the Brush Company before the option to purchase this concession could be secured. That cash had to be laid on the table before their Company came into existence, and therefore it was necessary for some individuals to come forward and find the £25,000. That company was formed, consisting of those individuals who speculated for a particular profit. The question was whether on the face of the prospectus on which all the original allotees applied for shares, there were fairness, frankness, and open disclosure of all the facts. The prospectus stated that the City and Suburban were the vendors and promoters of the company. It stated that the vendor company were to procure a transfer of the concession from the Anglo American Brush Corporation in consideration of £235,000, of which £175,000 was payable to that Company and £20,000 to the Hammond Company, thereby showing clearly what the total purchase money asked was and how it went. The prospectus further stated that the Memorandum and Articles of Association could be seen by intending subscribers, and that the City and Suburban Company would be dissolved immediately the purchase was completed. These facts were stated openly on the face of the prospectus, which constituted a contract with the Company, and on that state of things the capital was subscribed. With the exception of the chairman, whose acquaintance he had then only had for three weeks, all the other directors were entire strangers to him. When the directors met to consider the completion of the purchase, he said he was concerned for the vendor company, and it would be more agreeable to him if they appointed independent solicitors, and as to that matter he acted in no shape or way. With regard to the provisional orders he had acted for the Company, and he contended with eminent success. There were twenty-three provisional orders under a new Act of Parliament, so that they could see the work that had to be done. That work was done without the aid of counsel. He charged £50 for each order that was applied for, and £100 for each order that was obtained. He believed that was a fair scale of remuneration. Every transaction, so far as he was concerned, was perfectly open and above board, and no astute lawyer could find a single flaw in any of them.

Mr. W. ABBOTT thought that a committee of shareholders should be appointed, but not a committee of investigation. He had a horror of committees of investigation. They were generally initiated for the members of the committee to get on the Board, and he had seldom known directors born of a committee of investigation that were any good, and therefore he should strongly advise them in selecting the members of the committee to choose men who had a large holding. He warned them against allowing this Company to go to wreck just at the time there was a prospect of its bearing fruit. With the £100,000 of assets they possessed they had a fair chance of galvanising the concern into life and obtaining something out of the provisional orders. He was perfectly certain from what he saw was going on in electrical lighting matters that the provisional orders were fully worth what one speaker had put upon them. They should husband their resources, and they could utilise their uncalled capital to obtain money.

The CHAIRMAN said the directors would oppose the amendment for the appointment of a committee of investigation. He suggested that the report and accounts should be adopted, and that then a committee of conference should be appointed to have free access to the records and documents of the Company, including the cases and counsel's opinions referred to in the report, and to examine the accounts to November, 1883, that they should be at liberty to embody in their report such conclusions as they might come to, and at the expiration of twenty-one days from the date of their report, should they be dissatisfied with the attention given to their recommendations, they should be at liberty then to send in a requisition for a public meeting, which the directors should convene accordingly.

The amendment was then put to the meeting, and carried by a large majority.

On the CHAIRMAN putting it as substantive motion, another amendment was proposed, "That the report of the directors be and is hereby approved and adopted, and that the consideration of the accounts be postponed until after the report of the committee; and that a committee of shareholders be appointed to investigate the affairs and the prospects of the Company, and the circumstances attending its promotion and formation, with full power to call for documents, books, and papers, to examine the officers of the Company, past and present, and that such committee do report the result of their investigations and recommendations (if any) to the shareholders as soon as practicable."

This amendment was put and carried, and a committee of five shareholders having been appointed, the retiring directors and auditors were re-elected, and the proceedings then terminated. The gentlemen forming the committee are Admiral Sir E. Inglefield, and Messrs. Lawrence Engel, Hucks Gibbs, A. Peebles, and J. F. Andrea.

## NOTES.

EARTHQUAKES IN AUSTRALIA.—The *Colonies and India* says that sharp shocks of earthquake have been felt at Geraldton and Dongarra on the coast of Western Australia.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The coupons due on the 31st December next on the debentures of this company will be paid by Messrs. Barclay, Bevan, and Company. The coupons must be left three clear days for examination.

PANAMA CABLE INTERRUPTED.—A despatch from Panama, dated 24th December, says that, owing to the interruption of the West India and Panama cable between Jamaica and Colon, messages for Colon and Panama are now forwarded *viâ* Galveston.

LONDON-PLATINO BRAZILIAN TELEGRAPH COMPANY.—An extraordinary meeting of this company has been called to pass a resolution authorising the directors to provide funds for paying off the existing debentures of the company due on March 1, 1884.

THE TELEGRAPH IN WESTERN AUSTRALIA.—A line is being erected between Northampton and Roebourne in Western Australia. When completed this line will considerably lessen the gap which exists between Northampton and Port Darwin on this coast.

ELECTRIC LIGHTING IN SHEFFIELD.—Messrs. Joseph Rogers and Sons, of the Queen's Cutlery Works, Sheffield, are having their warehouses and workshops fitted up with Swan incandescent lamps. The current will be supplied by Siemens shunt-wound dynamos. Messrs. Tasker, Sons, and Co., electrical engineers, of Sheffield, have charge of the work.

M. ABDANK'S CALL BELL.—The magneto call bell, designed by M. Abdank-Abacanowicz, and described and illustrated in our issue of Sept. 1 last, was recently tried over the telegraph line between Lyons and Saint Etienne. The distance is 58 kilometres, and part of the line is laid underground. A French paper says the bell worked perfectly satisfactorily.

ELECTRIC LIGHT IN SWITZERLAND.—The Geneva correspondent of the *Daily News* says that the first town to be entirely lighted and have its tramcars driven by electricity will be Montreux, on the Lake of Geneva, a company having obtained a concession for the purpose. The motive power is derived from the water of the lake. Extensive works are to be erected immediately.

THE TELEPHONE IN BELGIUM.—The Compagnie Belge du Téléphone, who lately received a regular concession from Government, have been developing their system in Belgium with energy. They have increased the number of their subscribers by 278 within a short time. The total number of subscribers to the company's system in Belgium now is 2,040, divided as follows—Brussels 556, Antwerp 748, Ghent 272, Charleroi 208, Verviers 256.

NEW PAPER.—The first numbers of the *Elektrotechnische Rundschau* have made their appearance. This new recruit to the ranks of electrical journalism is issued every month, and enlisted in October last. It is edited by Dr. Theodor Stein, of the Frankfort Electrical Society, and published by Messrs. Mahlan and Waldschmidt of the same city. There are a fair number of illustrations in the first three numbers, and the *Rundschau* is well printed.

BOOKS RECEIVED.—"Electricity in Theory and Practice; or, the Elements of Electrical Engineering." By Lieut. Bradley A. Fiske, U.S.N. [Van Nostrand, New York, and Spon, London.]—Transit Table for 1884, giving the Greenwich mean time of the transit of the sun and of certain stars for every day in the year. By Latimer Clark. [Spon, London and New York.]—*Van Nostrand's Engineering Magazine*, October, November, and December, 1883. [Van Nostrand, New York.]

THE HAMMOND COMPANY.—We are informed that the business of the Yorkshire Brush Electric Light and Power Supply Company (Limited), and of Messrs. Ferranti, Thompson, and Ince (Limited) will in the future be carried on by the Hammond Electric Light and Power Supply Company (Limited), with which the above-mentioned companies are now amalgamated. The Hammond Company have appointed Mr. Thomas Smith their agent and representative for Yorkshire, his office being at 1, East-parade, Leeds.

EARTHQUAKE AT LISBON.—A strong shock of earthquake was felt at Lisbon at half-past three a.m. on the 22nd inst. Later news says that a slight shock was felt at 1:30 a.m., and was followed by a severer one at 3:30, which lasted twelve seconds; another report says fifteen seconds. The direction of the seismic wave is given by the *Standard* correspondent as "from east to west," whilst Reuter speaks of it as being "from north-west to south-east." Lloyd's agents confirm the *Standard* correspondent's account. But little damage was done, and that was confined to old buildings.

ASSISTANT EXAMINER IN THE PATENT OFFICE.—The Civil Service Commissioners announce that the following gentlemen have passed the preliminary examination for the situation of assistant examiner in the Patent Office, held in London on the 15th instant:—William Henry Dennis Clark, Alexander James Davidson, Henry Davis, Allen Charles Frederick Evans, Herbert Welch Halton, Joseph Hopla, Rhys Jenkins, Thomas East Lones, Bowman Henry Madden, Arthur William Marfleet, William James Orsman, Robert Comins Puckering, Albert Francis Ravenshear, William Robinson, Robert Henry Stevens, William Alexander Stiven, William Sumner, Alfred Sutton, John Henry Tomlinson, William Ward, William Thomas Whitley, Arthur Whitwell, and Henry Wall Wilkinson.

CABLE COMMUNICATION BETWEEN HOLLAND AND ENGLAND.—In the Dutch Parliament on the 22nd inst., M. Wintgens drew attention to the precarious state of the submarine cable connecting Holland with England. "He stated," says a Reuter's telegram, "that England did not fulfil the duties imposed upon her by the Telegraphic Convention. The Ministers of Commerce and Foreign Affairs declared that the English Government had not refused to consent to an examination of the cable, but that the state of the sea had hitherto prevented the vessel of the Submarine Company making such an examination. They stated that England had just as much interest as Holland in preserving good communication between the two countries, and would not lose sight of her duties. They added that the Netherlands Minister in London had been instructed to watch the question."

AN ICE PALACE FOR MONTREAL.—Some of our readers may remember that Montreal possessed an ice palace last year—that is, a large building entirely built of blocks of ice. It was devoted to all kinds of gaieties and amusements, and, to enhance its beauty, was lighted by arc lamps. It was a great attraction during its brief existence, and, we presume, paid as well as its builders could wish, for we see that another and similar palace is to be erected again this winter by a company promoted for the purpose. We are not told whether it is again to be lighted by electric lamps, but we may very

Digitized by Google

naturally conclude that such will be the case. Gas and ice do not seem to have much in harmony, whereas arc lamps and ice enhance one another's beauty. By the way, we wonder that our theatrical managers do not make more use of imitation snow and ice in combination with an arc light or two. The effect would, we venture to think, be very pretty, and the expense small.

Electric Light in Co-operative Stores.—The Junior Army and Navy Co-operative Society have just introduced the electric light on three floors of their premises, York House, Regent-street. The installation consists of seventy-five Gatehouse incandescent lamps of twenty candle-power nominal each, the current being derived from a $D^2$ Siemens dynamo machine driven by a 16 horse-power Otto gas engine. The work has been carried out under a contract by Mr. Fred. Croker, of 9, Margaret-street, W., the dynamo machine and lamps being supplied by the Pilsen Joel and General Electric Light Company. The order for the lamps and dynamo machine was delivered to that company on the 12th inst., at twelve o'clock noon. The machine was tested at the company's factories by Mr. Croker's electrician, at 2 p.m. on that day, and the installation was running satisfactorily on the 15th inst. The co-operative society are to be commended for the enterprise they have shown in the matter, theirs being, we believe, the first co-operative stores in London which has adopted the incandescent light.

Dangers of Overhead Wires.—We take the following from the *New York Nation*:—"After the experience in Fifth Avenue, on Monday evening, there is no necessity for further expert testimony concerning the danger from electric lighting wires. A runaway in the avenue broke down one of the electric lamp poles, and trailed the wire upon the pavement. A passing horse stepped upon the wire; there was a flash of purple light, a report like a pistol shot, all the lights in the Avenue went out, and the horse fell dead. A moment later another horse stepped upon the wire and dropped dead like the first. The Avenue was immediately closed to travellers of all kinds. Of course if a person had stepped upon the wire, he would have shared the fate of the horses. It was a stormy night, and there were few people upon the Avenue, or the consequences might have been much more serious. A wire which kills instantly every person who treads upon it would be a deadly thing for a crowd to surge over. Clearly the only safe place for these wires is under ground, and the sooner they are put there the better."

The Gramme Patent.—The British Electric Light Company have petitioned "Her Majesty in Council for a prolongation of the term of sole using and vending an invention of improvements in magneto-electric machines,' granted to Zenobe Théophile Gramme and Eardley Louis Charles D'Ivernois, both of Paris, France, by Her Majesty's Letters Patent, bearing date the 9th day of June, 1870, No. 1668, within the United Kingdom of Great Britain and Ireland, the Channel Islands, and Isle of Man, which said Letters Patent are now vested in the said British Electric Light Company." Notice is also given in the *London Gazette* that the company intend to apply by counsel to the Judicial Committee of the Privy Council, on the 1st March, or if the said Judicial Committee shall not sit on that day, at the next sitting of the said Judicial Committee after that date, for a time to be fixed for hearing the matter of the said petition; and that on or before the said 1st March, 1884, notice must be given of any opposition intended to be made to the said petition, and any person intending to oppose the said application must lodge a caveat to that effect at the Council Office, on or before that date.

The New Patents Act.—It is officially announced that no applications under the new Patents, &c., Act will be accepted if they bear a date prior to the 1st of January, 1884, the day upon which the Act comes into operation. Copies of the rules under the Act can be purchased at the Patent Office Sale Department, Cursitor-street, Chancery-lane. It will not be possible to place the forms for applications under the Act for sale at various post offices before the 29th December; but any persons, if they think fit, may prepare forms in manuscript in conformity with the rules. Referring to the foregoing official notice, "A Barrister of Fourteen Years' Standing" writes to the *Standard* as follows: "According to this notice, no application will be accepted if dated prior to the 1st January. The effect of this is simply that all inventors living abroad or in the country who, from poverty or other cause, cannot come to London, will lose their priority of application, and may thus be deprived of their legal rights under the Act. This is done by a high-handed process which has no justification whatever either under the Act itself, or under the rules just issued by the Board of Trade, and is altogether *ultra vires* and illegal. What makes this matter of pressing importance is that the issue of this notice has been delayed until the Law Courts have risen for vacation, which leaves no appeal except to the Press. If this be the way in which the new Act will be worked, the poor inventor, at any rate, will have little cause for congratulation on the recent change in the law."

Masters and Men.—On Monday last, December 24th, the firm of Verity and Sons, of King-street, Covent Garden, invited the whole of their workmen to dinner at the Holborn Restaurant. The dinner was given in the large room known as the Venetian room, and about a hundred enjoyed the festivities of the evening. The chair was taken by Mr. B. Verity, the senior partner of the firm. We are always greatly interested in these social gatherings of masters and men, believing that they do more to establish cordial relations between them than can be effected in any other way. Messrs. Verity and Sons have a claim upon those interested in the progress of the electric light, inasmuch, as being interested in the manufacture of gas and similar fittings, they saw that the electric light, instead of diminishing the class of work in which they had embarked their capital, would increase the demand, and they did not hesitate in its very early days to throw their energies and experience into the designing and making of electric light fittings. The great success they have achieved in this new branch of work will, we hope, be fully endorsed by those who see the result at such places as the Holborn Restaurant, Gatti's, &c. The most cordial relations exist between the heads of the firm and their *employés*, and there is no doubt, where it is the case that such mutual confidence exists, it adds greatly to the success of the firm in whatever work it undertakes. The dinner was well served, and was a credit even to such a gigantic restaurant as the Holborn, where, we understand, on the average about 1,400 people dine daily.

Measuring the Intensity of Powerful Lights.—If any strong light, like the electric light for example, is to be compared with a normal candle, the distance to which the former must be removed is inconveniently great. Dr. H. Hammerl has devised a very ingenious method of reducing the intensity of any light by purely mechanical means, cutting off one-half, three-fourths, or even nineteen-twentieths of the light, so that what remains is easily measured. It consists in placing in the path of the rays that fall upon the screen a revolving metallic disc, from which are cut sectors that allow a portion of the light to pass through, but cut off and absorb

Digitized by Google

the remainder. If the sum of the angles of all the sectors taken together equal 180 degrees, one-half of the light will be intercepted while the other half passes through. Experiments show that three sectors will suffice to give a uniform illumination with a moderate speed of revolution. The size of these sectors will, of course, depend upon the amount of light to be cut off. When it is desired to reduce the light to one-third, each sector must have an angle of 40°. If each sector have an angle of 12°, the light will be reduced to one-tenth, and so on. When two discs are employed each having three sectors of 60° each, they can be so arranged on the axis as to give any desired result. If a single disc is employed, the openings should not be true sectors having a definite angle at the centre, but cut so that the angle decreases from the centre toward the circumference in a definite ratio. This may be so chosen that the weakening shall regularly increase from centre to circumference just as the distance from the centre increases. When this form of disc is employed, the usual greased spot on the screen must be elongated instead of round, and as long as this opening. One end of this spot will be dark, the other light, and it must be noticed where this change occurs, and the amount of weakening read by a scale on the disc itself.—*Zeitschrift für Instrumentenkunde.*

Escaped Gas.—Not long ago the American papers had some amusing paragraphs on the subject of "Vagrant Electricity." A certain area of street was supposed to be highly electrified, and a great deal was made of the peculiar prancings of such horses as invaded this area. Subsequent examination into the affair somewhat toned down the highly-coloured reports, and showed that more than one half of what was written originated in the busy brains of the reporters, and had no foundation in fact. On other occasions we have seen spicy paragraphs detailing how the current has leaked from an electric light wire to now a lamp-post, now some railing, and now again a water-pipe, and relating the consequences to individuals in the vicinity of these ordinarily well-conducted adjuncts of civilisation. Many of these stories, all of which had, no doubt, some slight foundation of fact, have been taken up from time to time by the gas journals and made the most of. Electricity, said they, is dangerous, very dangerous, difficult to manage, a vagrant something, which might turn up anywhere at any moment, very much to the detriment of anybody in the locality, and more to the same effect. It is as well, therefore, we think to call attention to the fact that gas is by no means invariably the faithful servant that our contemporaries would like to make it out. Within the past few weeks we have seen recorded in the daily papers numerous instances of explosions of gas. One day it gets into a sewer, and suddenly the greater portion of the street is blown up, with disastrous consequences. Another day a householder has a room or two wrecked, or possibly the whole house blown inside out. Or, yet again, a high wind blows over a large gasholder or two, the escaping gas is ignited, and we hear of the flames shooting up into the atmosphere to a great height, "forming a grand but terrible spectacle." Gas may be useful, but it is as well to remember that it is decidedly dangerous, far more so we think than electricity.

Cafe Lighting.—Messrs. J. H. Holmes and Co., electric light engineers, of Westgate-road, Newcastle-on-Tyne, have lately completed a very satisfactory installation at a new café recently opened at Wallsend-on-Tyne. The installation comprises two dynamos driven by means of a six horse-power Tangye vertical engine supplied with steam from a large vertical boiler. The engine is mounted on the same bedplate as the boiler, and is provided with a high speed Pickering governor. The larger machine is a Siemens SD 2 self-regulating dynamo, and furnishes the requisite current for sixty 20 candle-power Swan lamps arranged on specially designed fittings in the café proper, the news room, billiard room, game room, halls, and staircases. The fittings, which are mostly combined gas and electric, comprise six electroliers of elegant design, together with a substantial six-light billiard pendant and a number of single light brackets. Round the windows of the café runs a massive tube, carrying at intervals fifteen special brackets, together with gas jets, to be used in the early morning, when the machinery is not running. On the outside front of the building are placed two arc lights in spherical lanterns, supported by means of hinged brackets in such a way that they may be swung round in front of a window, from which they may be reached for the purpose of renewing the carbons, &c., thus doing away with any need for ladders or hoisting apparatus. Arrangements are made for hanging one of these lamps, when required, in the concert hall, which forms part of the building, and when thus used it is found to light the room admirably. It is also intended to use this lamp for working a magic lantern in the hall when required for illustrating lectures, for school treats, and such like occasions. Amongst the novelties of this installation may be mentioned an arrangement by which the electric current is utilised for the simultaneous lighting of the sun burners in the ceiling of the concert hall. This is done by rendering incandescent several small coils of platinum wire near each burner. The circuit is completed through these coils on pressing a push similar to those used for electric bells. The arc lights are supplied from a small alternating current machine, driven from the flywheel of the engine. Both lamps are Siemens' differential type, and burn very steadily.

Barnett's Accumulator.—On Christmas eve we were invited to see a new accumulator, the invention of Mr. H. T. Barnett, which has for two or three months past been supplying current to a number of incandescent lamps in the offices of Mr. Spagnoletti, telegraph superintendent to the Great Western Railway Company at Paddington. It is not easy to centre one's mind on accumulators with the prospect of a hard-earned holiday so close at hand, and we did not, therefore, do more than make a few notes based on Mr. Barnett's own statements as to the capacity of his cells, which notes we must ask our readers to rest content with until we have an opportunity of giving them some further details based on tests made by ourselves. Mr. Barnett appears to have made some decided advances in the direction of a good accumulator, the anxiously sought-for-goal of dozens of hard-thinking electricians. The materials used are lead plates with finely divided lead packed in between in horizontal layers separated by felt, a porous plate separating two electrodes. Mr. Barnett states that the loss of current in charging and discharging, as ascertained from careful tests taken at Paddington during ordinary work, is less than 10 per cent. These tests were made with the old experimental set of cells which have been constantly at work for over nine months. The E.M.F. of the battery is $2\frac{1}{4}$ volts per cell, and this E.M.F. remains constant for 7-9ths of the time of discharge, after which it drops to 2 during another 1-9th, and then sinks to zero. The battery is practically dry, the only solution required being contained in the pores of the active matter and felt. The solution is used very acid. These batteries are quite solid, and will stand shaking and rough usage without any danger of spilling acid or short-circuiting internally. The active matter Mr. Barnett assured us cannot become separated

Digitized by Google

from the conducting lead plate either mechanically or electrically, as during formation the divided lead swells very much, and is kept in the best possible contact with its conductor. The battery is, Mr. Barnett claims, the smallest in size, in proportion to its power, which has yet been produced. It is proposed to use these batteries for railway-train lighting. The cells are to be provided with foot-plates, so that by simply placing the battery in its position in the train (as a foot-warmer might be) the connections are made and the lamps lighted. Each battery will maintain a 12 candle-power Swan lamp from 10 to 20 hours, and measures 1ft. 10in. by 7in. by 6½in. outside measurement. These accumulators require full current for one week to form them. Mr. Barnett has also introduced in connection with his battery a neat and ingenious automatic cut-out, by which the cells are switched into the charging circuit directly they are in the least discharged, and switched out again when recharged, whilst the break in the charging circuit is bridged over at the same time.

An Automatic Cut-out.—At a recent meeting of the Franklin Institute of Philadelphia, an automatic cut-out, devised by Messrs. Pinkham and Seal, of that city, for preserving an open circuit battery from ringing when accidentally short-circuited was described as follows:—A strong magnet of low resistance controls an armature, which in turn operates an insulated cylinder by means of a connecting rod. Attached to the upper end of this cylinder is the segment of a cog-wheel, which engages in a smaller one bearing a fan, the object of which is to offer sufficient resistance to the armature to cause it to move slowly. The outer surface of this same cylinder, which is about ⅝in. in diameter and about 1in. long, is faced with platinum, against which three fingers, secured to a post of rubber or other insulating substance, come in contact. These fingers are made of a good conductor, possessed of more or less elasticity. The first finger plays upon the platinum surface above described the entire limit of its partial revolution, caused by the action of the armature. The second finger plays upon the platinum until the armature is drawn nearly up to the magnet heads, when it becomes insulated by a piece of rubber passing under it. The third finger is the reverse of the second, being insulated from the cylinder until just before the second finger becomes disconnected, when it comes into contact with the platinum surface. No. 1 finger is connected with one wire of the magnet, the other wire being attached to a binding post in the instrument. Fingers No. 2 and 3 connect with two more binding posts. A weight is secured to the cylinder in such position that when the magnet ceases to be energised the armature is carried back to its normal position. The instrument is attached as follows:—The magnet is looped into the ground wire of the battery by means of the two binding posts. This disposes of fingers 1 and 2, which are always in contact on the platinum surface when the magnet is not energised. The other binding post is attached by wire to the same pole of a gravity battery, which corresponds to the ground wire of the open circuit battery. The other pole is attached to the same wire of the opposite pole of open circuit battery. This disposes of No. 3 finger. The action of the instrument is now very simple. Any vibratory connection, such as ringing a bell or lighting an automatic gas burner, has no effect whatever upon the instrument. A single contact, such as is caused when ringing a stroke or tap bell, or lighting a burner by the wire spark (so-called), produces a slight impulse in the instrument; but should the contact be sustained for one-fourth of a minute, the energised magnet attracts the armature which revolves the insulated platinum surface, causing a change of connections. When at rest, fingers 1 and 2 are in contact; when energised, fingers 1 and 3 are in contact. No. 2, which connects with open circuit battery, has now become insulated; and No. 3, which connects with closed circuit battery, has come into contact with No. 1, or ground wire. In this instrument the ground is not removed; but the circuit is simply changed from a battery which will be destroyed, if grounded a sufficient length of time, to a battery whose nature is the reverse, and would therefore carry the ground without destruction so long as it has material to work upon. To preserve the closed circuit battery in a normal condition while not in use, it is close circuited through a coil of very high resistance, which allows just enough current to pass through the battery to retain its strength. Now, should the ground be removed by accident or otherwise, the magnet loses its energy, and the armature is carried back to its normal position by the weight on the cylinder. The instrument is actuated upon by the open circuit battery up to a certain point, when the closed circuit battery is thrown in, and retains the armature at that point until the ground is removed, thus opening the circuit of the destructible battery.

Underground Wires in New York.—The following letter from Mr. W. C. Behrens, secretary to the General Committee on Underground Communication in New York, appeared in a recent issue of *The Times*:—"I beg to call your attention to the thoroughness with which the very difficult work undertaken by the General Committee on Underground Electric Communication of this city is being carried out. This committee is composed of twenty-four members, representing (with the sole exception of the Western Union Telegraph Company) all the telegraph, telephone, electric light (arc and incandescent), district messenger, burglar alarm, signal, and time telegraph companies. The problem which it has undertaken to solve is to place all wires of the telephone system, of the several different systems of telegraphic communication, and of the several systems of arc and incandescent electric lighting (systems greatly varying in electromotive force used, and in character and strength of current) in a single conduit or way, and—what is absolutely essential—in a manner so as to be inductively independent of each other, and practically free from retardation. This has never before been attempted. As an example of the necessity of securing freedom from induction and retardation, the telephone may be cited. Being extremely sensitive, it responds to electrical impulses of many thousands in a second, and it is essential that no substantial modification of the electrical impulses shall take place during transmission. As induction varies inversely as the square of the distance, it is evident that the necessary proximity of a large number of telephone, telegraph, and electric light wires in a single underground conduit would very greatly increase the existing annoying interference from induction, not only from the telegraph and electric light wires, but from other telephone wires. With any considerable length of wires comes retardation, due to increased electrical capacity, and, as is well known, an enormous increase of capacity results when an insulated wire is placed underground. Retardation not only delays, but modifies and distorts the signals. The sound produced by the voice must preserve certain and great rapidity of change, and when retardation is so great that signals cannot be transmitted with this necessary rapidity then said sounds are so imperfectly reproduced as to become partially or wholly unintelligible. The burglar alarm telegraph central office system is based upon the use of a continuous current of constant quantity and intensity, in

Digitized by Google

connection with a delicately-constructed galvanometer. Any deflection of its needle, caused by induction destroying the constancy or changing the intensity of the current, gives a false alarm, and thus induction destroys the entire system. The service of the time telegraph, at present employing a metallic circuit, exacts perfectness of operation, and is such that occasional failure of working, except at very long intervals, would be fatal to its usefulness and its existence. Freedom from breakage, leakage, heavy induction, defects n insulation, and ground connection is, therefore, absolutely essential. The particular requirement of the district telegraphs (messenger service) is facility for making connection with every house without disturbing the pavement. Metallic circuits are employed of a length not exceeding one or two miles. These will serve as illustrations. The conduit must be of large capacity and of a practicable form and size, in cross-section. If naked wires are employed, moisture must be excluded from them and from all connections. If insulated wires are used, the character of the insulation will determine the necessity of its exclusion. The details of construction must be such as to permit immediate connection or repeated changes with every house or building for all kinds of electrical service, access for repairs and testing, and the laying of additional wires without removal of the pavement. More than 600 patents and devices have been examined, and correspondence with learned societies and individuals throughout the world has resulted in the collection of an immense amount of valuable information. An ideal system is not yet evolved from these investigations, and it will be of the greatest interest to every municipality that all sources of information be placed at the disposal of the committee. Messrs. Woodhouse and Rawson have consented to act as agents for the committee in examining and forwarding matter relating to electrical and mechanical devices, and the Hon. Mark Francis Napier, of counsel, may be referred to in matters pertaining to the law."

Science and Art.—Dr. Ray Lankester, commenting on Sir Charles Dilke's recent speech to the Science and Art students at Hammersmith, writes to the *Pall Mall Gazette* as follows:—"Such views are widely spread and accepted, though, as it seems to me, they are based on misapprehension, and likely to retard the progress of civilisation in any community which is influenced by them. To contrast science and art as contending interests is, I venture to think, a mistake; they are not reciprocally exclusive, but rather do they aid and supplement one another. When it is asserted that science can take care of itself—which means, presumably, that science is self-supporting—it is obvious at once that the speaker is alluding by the word 'science,' not to science in the modern sense, but to 'invention.' It is now usual to understand by the word science that natural knowledge or knowledge of the order of nature, to promote which the Royal Society was founded some two hundred years ago. The search for this knowledge never has taken care of itself and never can do so. The discoveries of those who carry on this search are never made a matter of trade. Davy, Œrsted, Faraday, Pasteur, and Lister did not take care of themselves; they absolutely and freely gave their discoveries to the world. Among others to whom Œrsted and Faraday gave their discoveries were the 'inventors' of the electric telegraph and the dynamo-electric machines. Inventors, it is true, do take very good care of themselves; aided by our patent laws they make fortunes. It might be supposed that, full of gratitude to science, these inventors would voluntarily pay for their appropriation of other men's discoveries by devoting some part of their wealth to the support of scientific research. They never do so. I do not know of a single instance in which the great inventors, electricians, and others, who are set before the public by mistake as representatives of science (whereas they are only the commercial adapters of other men's discoveries), have given money to the support of science. So little is science capable of taking care of itself that in this country, at any rate, she submits to not only the utilisation of her results by men who seem to be devoid of all sense of gratitude, but also to these same men usurping her titles and dignity after they have helped themselves (without the smallest intention of making any return) to the fruits of her toil. I have no wish to exalt unduly the claims of science—that ever-growing knowledge of nature which is the direct and indispensable antecedent of inventions—above those of art, understanding by this term what are called 'the Fine Arts;' but I think that in self-supporting capacity art is fortunate at the present day as compared with science. I should have expected Sir Charles Dilke to appeal on that ground for sympathy and aid first for science, for art can take care of itself. Surely the men who correspond to the inventors make a very good business in art. The men who adapt the work of great artists to our daily wants, the house decorators, printers, popular musicians, and such like, not to mention the art-critics, are a thriving class. And in art, the greater men behind these interpreters, they who create or resuscitate, seem to be generally well provided for. The art-interpreters are not allowed to appropriate the creations of those artists who occupy a position parallel to the makers of new knowledge. The original artist does not, like the original explorer in scientific matters, give his work when done to an ungrateful public; he sells it for a sum of money. In this respect it seems to me that art necessarily is in a far more favourable position than science. It is right that a man should be paid for his labour, and that within limits he should be stimulated by the prospect of pecuniary reward to activity. Private inclination provides such support to the artist; the enjoyment of a picture or of music is an object to individuals, although it is not of much importance to the community at large that these individuals should enjoy constantly a large amount of the best painting and music. On the other hand, private inclination (naturally enough) does nothing for science in the way of pecuniary support. No one would think of buying a discovery (not, be it noted, an invention) from a Faraday or a Pasteur, in order that he might keep it in his dining room and display it to his friends. While art has its value for the individual and is supported by him, the results of science are of value, not to individuals, but to the whole community, in a way and to a degree to which those of art do not make any approach. The discoveries of science are freely circulated in all civilised lands, they are gradually assimilated and turned to account; the startling scientific result which astonished one generation becomes in the next, in other hands, the pivot of a great manufacture, the saviour of life, or the key to a world-old mystery. While art has its natural and ready support in the willing payment of those who seek its pleasures, science receives no corresponding maintenance. It is to the State that science is of value, and it is by the State that science must be supported. The day when the State will fulfil this obligation may perhaps be hastened if the proposition that 'Science can take care of itself'—a proposition which seems like a cruel mockery when we survey the facts of the case—be contraverted as often as it is publicly endorsed by a statesman."

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 127.)

**Distribution of Current in Electrolytes.**—With a perfectly homogeneous electrolyte of much larger section than the opposed surfaces of the electrodes, and the latter placed centrally and symmetrically in it, when the current leaves the anode it spreads out in the liquid in curves not unlike those of magnetism diverging from the poles of a magnet, and the densest portion of the current is in the central axis joining the electrodes. Its distribution in the liquid has been investigated by Tribe, who suspended little bits of metal in different parts of a cross section of the solution, and ascertained the amount of electrolytic action produced upon them by the same current, during the same period. (*Proceedings Royal Soc.*, Vol. XXXI., p. 320; Vol. XXXII., p. 435.)

**Relative Amounts of Currents produced by Different Metals.**—Equal weights of different metals yield by voltaic action different amounts of current. Whatever amount of current a particular weight of any given metal requires in order to deposit it, that same amount will it yield by voltaic action; its generating and consuming powers in relation to electric current are therefore equal. The amount of current produced by a given weight of a particular metal depends both upon the atomic weight and upon the degree of valency of the metal. An atomic weight of a monad metal yields one equivalent quantity of current; one of a dyad yields two; a triad three; and so on.

The percentage of equivalent of external current actually obtained is, however, in practice extremely variable, and the full proportion is rarely obtained. This arises from the circumstance that a greater or less proportion of the current generated circulates in minute local circuits upon the surface of the dissolving metal, and does not enter the external circuit at all. By actual experiment in nearly one hundred cases of various kinds, I found that the proportion of external current varied from about 2 to nearly 100 per cent.

**Electrolytic Arrangements.**—Various combinations and arrangements have been employed in which chemico-electric currents produce electrolysis; and these arrangements have been classified as follows:—1. Electrolysis by simple contact of one metal with one liquid; 2. By contact of one metal with two liquids; 3. By contact of two metals with one liquid; 4. By contact of two metals with two liquids; 5. By a separate electric current; and 6. By a separate current and a series of electrolysis vessels.

The first of these arrangements is termed the "simple immersion process," the most familiar example of which is the coating of iron with copper by simply dipping it into a solution of cupric sulphate. In this process the voltaic currents are excessively minute, are generated in immense numbers at points inconceivably small all over the immersed surface of the metal, and re-enter producing electrolysis at all the intermediate points of that surface. In this arrangement the actions and products at the anodes cannot conveniently be observed or separated from those at the cathodes. The deposit of metal obtained by it is usually very thin.

The second consists in either carefully placing a lighter liquid in a distinct stratum upon a heavier one, or separating the two by means of a porous partition, and immersing the metal in contact with the two liquids. The portion of metal in one liquid then generates a current which re-enters the other part, or the second piece of the same metal in the second liquid, and produces electrolysis. By this contrivance the negative portion of the metal receives an electrolytic deposit in a liquid which the metal itself is unable to decompose by simple contact.

The third consists in bringing two metals into contact at their upper ends, either without or by means of a wire, and immersing their lower ends in the liquid; or allowing the metals to touch each other in the solution. Under these circumstances a current passes from the positive metal through the liquid into the negative one, producing electrolysis, and returns by the external circuit; the positive metal also acts simultaneously by "simple immersion process." This contrivance also enables the negative metal to receive an electrolytic deposit in a liquid which it does not decompose by "simple immersion," because the second metal offers a second path of return for the re-entering current. Cases of self-depositing metals acting by this process have long been recorded, in which a metal immersed in a solution of the same metal has produced a metallic deposit, *e.g.*, with cadmium in contact with copper in a boiling hot saturated solution of cadmic chloride, the copper becomes coated with that metal. These cases have been but little investigated. Under this arrangement may be classed the "two metal" couples of Gladstone and Tribe, in which the resistance is greatly diminished, and therefore the strength of the current increased, by making the circuits indefinitely small. This is effected by electrolytically depositing copper, silver, or platinum in a porous spongy layer upon the surface of zinc or magnesium, washing the plate so prepared, and immersing it in the liquid to be electrolysed.

The fourth is termed the "single cell process," and consists of two liquids separated by a porous partition, the two metals being partly immersed, one in each liquid, and in contact with each other externally, or connected together outside by means of a wire. This method also enables a deposit to be produced upon a metal which does not decompose the liquid by simple contact. In this and the second arrangement, however, the liquids gradually diffuse into each other, waste the positive metal by simple immersion process, "and disturb the action at the negative surface."

The fifth is the most convenient arrangement, and the most frequently employed. It consists of a vessel containing the electrolyte and two electrodes, neither of which spontaneously decomposes the solution, the electrodes being connected with the battery or other source of current by means of two wires. It is known as the "battery process," or "separate current process." By it the strength of current in relation to the resistance in the electrolysis cell may be indefinitely increased, the most incorrodible metals may be used as anodes, and with a sufficiently dense current and suitable liquid even the alkali metals may be deposited. The sixth arrangement consists merely of a single series of such vessels and electrodes with an undivided current passing through the whole of them. It is not much employed.

**Self-Deposition of Metals.**—Raoult, also Gladstone and Tribe, have discovered some new cases of electrolysis of his kind. Raoult states (*Comptes Rendes*, Vol. LXXV., p. 1,103) that when two plates, one of copper and one of cadmium, are completely immersed in a solution of cadmic sulphate deprived of air, and covered with a layer of oil, as long as they do not touch each other, a very slight evolution of hydrogen is seen on the cadmium plate, whilst the copper shows no visible change. When, however, the plates are caused to touch each other, cadmium at once begins to be deposited on the copper one. Couples of gold iron, gold nickel, gold antimony, gold lead, gold copper, or gold silver, immersed either in cold or hot acid or neutral solution of salts of the more positive of these two metals, yielded no deposit of that metal (*Journal of Chemial Society*, 2nd series, Vol. XI., p. 464). Gladstone and Tribe also observed that a copper zinc couple separated zinc from a 1·5 per cent. aqueous solution of zinc sulphate (*Ibid*, p. 453). Other instances of self-deposition will be given.

As these deposits of cadmium and zinc did not appear in solutions of the nitrates of those metals, and as an oxide of metal appears to be formed upon the corroded or positive plate, a probable explanation of the formation of the metallic deposits is that the water is decomposed, the salts in contact with the negative plate are reduced to the metallic state by the nascent hydrogen, and the acid thus formed is prevented from corroding the deposited metal by being immediately removed from it by diffusion into the mass of the liquid. Another arrangement in which a metal deposits itself is well known. It is that in which one metal is in con-

Digitized by Google

tact with two different liquids, one of them being a solution of a salt of that metal.

Methods of Preparing Solutions for Electrolysis.—The exact details of preparing solutions for electro-chemical action differ of course in every different case. There are, however, two general methods—the one termed the chemical, and the other the battery or separate current process. In the former the usual processes of oxidation, crystallisation, solution, &c., are employed, and may be found sufficiently described in any work on general chemistry. The latter usually consists in taking a suitable solvent, hanging in it a large anode of the particular metal and a proper cathode, and passing a current until sufficient of the metal is dissolved and the liquid yields the desired deposit. The liquids obtained by the two processes, however, are not always exactly the same in chemical composition, because the electric process is attended by chemical changes at the cathode. In the latter process the anode is sometimes immersed in a portion of the liquid in a porous cell, the latter being partly immersed in the remainder of the solution.

Electro-Chemistry of Individual Substances.—Usually, electro-negative bodies appear at the anode, and electro-positive ones at the cathode; iodine, however, also sulphur, and less frequently selenium, appear either at the anode or cathode, according to the electric character of the body it is separated from, and in rare cases the same element is liberated at both electrodes simultaneously, *e.g.*, iodine from an aqueous solution of iodic acid.

The degrees of facility with which different substances are separated from their compounds, and the conditions of electrolytic balance of substances at their points of commencing separation, are subjects which have been but little examined, and require much investigation. Extensive tables will yet be formed showing the degrees of electromotive force in volts, and the density of current required, to separate particular substances from certain liquids, under given conditions. General truths will thus be evolved, throwing light upon the magnitude of the influence we term "chemical affinity," and upon the molecular relations of bodies, showing us also why some substances are easy and others difficult to separate. A systematic examination of the conditions under which allied substances, particularly chlorine and oxygen, are set free, would probably enable us to determine those under which fluorine could be liberated. It is not by misdirected strength of current, however great, particular bodies are obtained, but by properly directed energy. From a weak solution of a potassium salt even the strongest current with a large solid cathode will not secure to us the metal, but by using a cathode of mercury of small surface, even by means of a current of low electromotive force, potassium has been isolated. The laws of nature are universal, and electrolysis is no exception to the truth of the general statement that the chief secret of success in all things is well-directed energy.

As the study of electro-chemistry includes a knowledge not only of the conditions under which a given substance is electrolytically separated, but also of the electrolytic effect of a current on individual compounds, both are described in the following sections, and the series of substances are treated in systematic order.

(TO BE CONTINUED.)

---

ELECTRIC LIGHTING AT RINGWOOD.—A small industrial exhibition, organised by Lord Shaftesbury at Ringwood, in Hampshire, is lighted by arc lamps. The contractors for the lighting are Messrs. Woodhouse and Rawson, of 11, Queen Victoria street, E.C. Six Pilsen lamps are used altogether, the current being supplied by a Schuckert dynamo driven by a portable engine, not remarkable for steadiness. The light given was satisfactory. Messrs. Woodhouse and Rawson also exhibited a small incandescent lamp, for microscopical purposes, the current being supplied by a battery, which also fed a surgical lamp of very minute proportions, burning inside a small tube filled with water.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 184.*)

All friction brakes are only applicable to absorb a limited amount of power, or, speaking more corectly, if it be attempted to absorb very large powers by these instruments, it becomes necessary to design them of such enormous size that they get too unwieldy and expensive. But large powers, especially in electrical engineering, are the order of the day, and it may confidently be expected that at no very distant date there will be electric light stations established where 1,000 and more indicated horse-power is required during the busy hours of the evening. The testing of prime movers for electric light stations will, no doubt, become an important part of the work to be done by electric light engineers, and therefore the description of a dynamometer suitable for absorbing very large powers should find a place in these articles. Such an instrument is the late Mr. Froude's turbine-dynamometer, originally designed for the testing of marine engines, but equally applicable to all kinds of powerful prime movers.

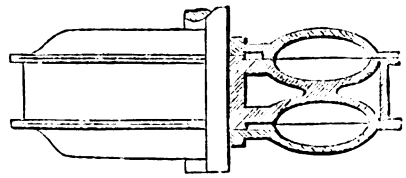

FIG. 15.—Froude's Turbine Dynamometer.

This dynamometer consists of two semi-elliptical rings cast back to back in one piece, and keyed to the brake shaft, and of two casings, also in the shape of semi-elliptical rings, placed on either side of the former, so that a radial section shows two complete ellipses (Fig. 15). Two are employed in order to avoid side thrust on the shaft. One half of each ellipse is formed by the inner wheel, the so-called turbine, the other half by the outer casing. The two ring-shaped cavities are subdivided by diaphragms, semi-circular in outline (and consequently set obliquely so as to fit into the semi-elliptical rings), and thus all round the circumference within turbine and casing a series of cells is obtained. A few of these are shown in Fig. 16.

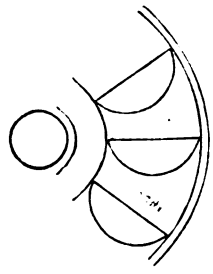

FIG. 16.—Froude's Turbine Dynamometer.

Imagine the apparatus filled with water, the casing, which is loose on the shaft, held stationary by means of a weighted lever and the turbine revolving with the shaft. Through the action of centrifugal force the water is driven from the inner to the outer circumference of the turbine, and thence enters the casing, pushing the water already there to the inner circumference of the latter, and from there again into the turbine. If there were no diaphragms the elliptical ring of water would revolve round the shaft with something like half the speed of the latter, and in addition would have a rolling movement upon itself, somewhat similar to that which might be produced in a rubber ring by twisting it inside out between the fingers. But through the presence of the diaphragms this comparatively smooth rolling movement of the water is changed into very violent shocks occurring at those places where the water passes from the

* In Fig. 10, of last article, the short ends of the jaws in Deprez's brake should have been shown connected by a bolt.

Digitized by Google

turbine into the casing, and *vice versâ*. The diaphragms in the turbine carry the water forward with a speed nearly equal to their own speed, and in so doing experience a pressure on their front side due to the acceleration of the water. The speed with which the water sweeps round the semi-elliptical outline and up the diaphragm of each cell will be the greater (other things being equal) the smoother the surfaces are. Having entered the cells of the casing at a high velocity, the water is forced to change its direction of flow, and in so doing exerts pressure on the faces of the diaphragms in the casing. On the other hand, this change of direction causes the water in re-entering the turbine to strike its diaphragms with increased force, and to become, consequently, further accellerated. In this manner turbine and casing re-act upon each other in the sense of mutual accumulation, and were it not for the friction of the water against the surface of the cells, there would be no limit to the violence with which the water would be thrown from one to the other. Thanks to this principle of mutual accumulation this brake is able to swallow up enormous powers. A turbine of only 5 ft. diameter having twelve cells can absorb 2,000 horse-power at 90 revolutions. It is evident that the temperature of the comparatively small mass of water contained within the turbine would quickly rise to boiling point if the heat were not carried off. This is done by placing the whole apparatus into a large tank of water. The couple by which the casing is prevented from rotating is equal to the torque of the shaft, and this varies as the square of the speed. The proportion between these values can, however, be varied by inserting sliding shutters between turbine and casing, so that part of the cells become covered, the power of the apparatus being diminished through the check thus given to mutual accumulation.

There is a curious analogy between the turbine-dynamometer and a series-wound dynamo working shortcircuited. The rougher the surfaces in the turbine, or the greater the obstruction caused by the shutters, the sooner will the limit of accumulation be reached. Similarly, the greater the specific resistance of the wire on the dynamo the less power will be required to work it shortcircuited. Now, imagine the wire of high resistance (say German silver) gradually replaced by copper wire, then the power absorbed at constant speed will as gradually increase just as the power absorbed by the turbine increases with the withdrawal of the shutters. To carry the analogy still further, a shortcuited series wound dynamo, the field magnets of which are supported separately from the armature, and are prevented from turning by some sort of balancing lever, which serves to measure the torque, is the electrical counterpart of Froudé's turbine dynamometer.

It was remarked in the beginning of these articles that absorption dynamometers are more particularly applicable for the testing of prime movers or power-producing machines, but that they can also indirectly be used for testing power-absorbing machines. A case in point is an experiment very frequently made by agricultural engineers to ascertain the power necessary for driving thrashing machines. This is done in the following way:—A portable engine and a thrasher are put in position and worked under normal conditions, care being taken to maintain water-level in the boiler, steam pressure, load on safety valve, position of stop-cock (which is generally full open during tests), adjustment of governor, and speed of engine as constant as possible. Precaution is taken to have no slip in the belt. Whenever practicable, indicator diagrams are taken during frequent intervals, and as an additional check on the power developed by the engine the quantity of coal and water consumed is carefully noted. Now, without altering any of the working conditions of the engine, the thrashing machine is removed and replaced by a brake, which must be so loaded that with an equally tight belt the former speed of engine is again obtained. Another set of diagrams is now taken, water and fuel as well as steam pressure and all the other conditions influencing the power of the engine are again noted, and if necessary altered, until everything is as before. In this case the power absorbed by and measured on the brake is equal to that which was necessary to drive the thrashing machine. In the same manner a dynamo can be tested if driven by a separate steam engine of convenient power. If driven by a turbine similar tests can be made, the working conditions to be noted and kept constant in this case being level of head and tail race, opening of gates, or regulating valves (if any), adjustment of governor, and speed of turbine shaft.

The number of cases in which measurements by absorption dynamometers are useful or necessary is so large and varied that even a mere enumeration of them would be beyond the scope of these articles, which are chiefly meant to be descriptive. But one example interesting to electricians might be given to show how a brake dynamometer can be used to test electro-motors. Apart from a complete investigation of a given electro-motor, there are the following two questions of practical importance which can be solved by using a brake in conjunction with the usual electric measuring apparatus. First, what is the maximum of mechanical work that can be obtained? and, secondly, what is the maximum of commercial efficiency of the given motor? By the term commercial efficiency is meant the ratio between work received on the brake and the mechanical equivalent of electrical work absorbed by the motor.

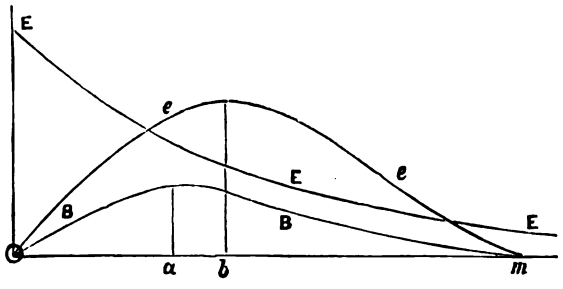

FIG. 17.

To fix the ideas we will assume that we have a practically unlimited supply of electricity delivered at a constant electromotive force, such as would be obtained from the mains in a system of town supply. The faster we allow the motor to run the less current it will pass, and since the pressure in the mains, and consequently at the terminals of the motor, is constant, the less electrical horse-power will be absorbed by it. Let in Fig. 17 the speeds be plotted as abscissæ, and the electrical work absorbed in units of volt-amperes divided by 746 as ordinates, then with a series-wound motor we obtain the curve E E. The exact shape of this curve depends, of course, on the construction of the motor, but its general character will be as shown. Variation in speed must be obtained by loading the brake to different weights. We begin with an excess of weight, which will hold the motor fast, and then a maximum of current will flow through it without producing any external work. On the other hand, if we remove the brake the motor will run with a maximum speed, and again produce no external work, but in this case very little current will pass. Between these two extremes external work will be done, and there is a speed at which this is a maximum, and also a speed (not necessarily the same) at which the commercial efficiency is a maximum. To find these speeds we load the brake to different weights and plot the resulting speeds and horse-powers as abscissæ and ordinates producing the curve B B. From the two curves E and B, another curve $e = \frac{B}{E}$, giving to an arbitrary scale the commercial efficiency, can be obtained. By means of these three curves we find the answer to the questions cited above. The maximum of speed which the motor can attain when running empty is represented by the line $o\,m$, the speed at which it will yield a maximum of external, that is, useful horse-power, by the line $o\,a$, and the speed at which its commercial efficiency is best, by the line $o\,b$.

## A FEW NOTES ON HOW TO CALCULATE THE WIDTH OF BELTS.

BY E. KRAUSE.

The means at present most used to drive dynamo machines are belts and ropes, and as the required power sometimes amounts to not inconsiderable value, it is important to be able to calculate the size of the belts, keeping in view the mechanical laws under which the belts work.

It is necessary to consider at first a pulley with a belt strained over it. The friction of the belt on the circumference of the pulley gradually increases the tension $t$ on one end of the belt with the length of the arc of contact, and amounts at the other end to T, thus giving $T > t$. The relation of these two tensions will be seen from the following consideration:—

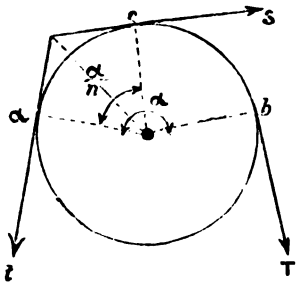

Fig. 1.

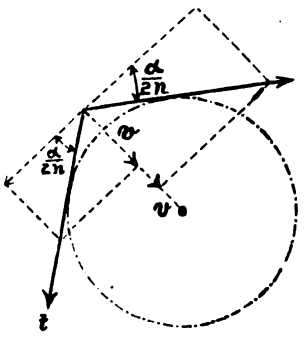

Fig. 2.

Let, in Fig. 1, the arc of the belt's contact with the pulley between the points $a$ and $b$ be called $\alpha$; the tensions of the belt acting in a tangential direction at these two points have been called $t$ and T. Consider a small part $\frac{\alpha}{n}$ of the arc $\alpha$; the corresponding tangential tensions of the belt in $a$ and $c$ may be called $t$ and $s$; then the parallelogram of forces may be completed as Fig. 2 shows. We get the vertical components

$$v = t \sin \frac{\alpha}{2n} \text{ and } V = s \sin \frac{\alpha}{2n}.$$

If the arc $a\,c$ is very small, we may put, without great error, $\frac{\alpha}{n} = d\alpha$, and $\sin \frac{\alpha}{2n} = \frac{\alpha}{2n}$, and, calling $d\,t$ the difference between the tensions $s$ and $t$, we have

$$d\,t = s - t, \text{ or}$$
$$t = s - d\,t.$$

The vertical components $v$ and V indicate the force with which the belt is pressed against the pulley, therefore the total normal pressure is

$$v + V = t \frac{\alpha}{2n} + s \frac{\alpha}{2n} = (t + s) \frac{\alpha}{2n}.$$

Putting the value for $t$ in the equation we get

$$v + V = (s + s - d\,t) \frac{\alpha}{2n},$$
$$= s\,d\alpha - d\,t \frac{d\alpha}{2}.$$

Neglecting the magnitude of the second order we get the total normal pressure to

$$v + V = s\,d\alpha.$$

But the friction of the belt on the pulley is normal pressure multiplied by the friction co-efficient $\mu$; therefore

$$\text{friction} = \mu\,s\,d\alpha.$$

It is obvious that the difference of the tensions $s$ and $t$ is equal the friction of the belt on the pulley, and we have therefore

$$d\,t = \mu\,s\,d\alpha.$$

We find in like manner the friction of the belt on the whole arc $\alpha$ by adding all these values—that is, by integrating them between the limits $t$ and T. We have

$$\int_t^T \frac{d\,t}{s} = \int \mu\,d\alpha, \text{ or}$$
$$\text{hyp. log } (T - t) = \mu\,\alpha, \text{ or}$$
$$\frac{T}{t} = e^{\mu\alpha} \quad \ldots\ldots\ldots \quad (1).$$

The friction co-efficient $\mu$ for ordinary belts on iron pulleys is, after Morin, 0·3 for ordinary belts, and 0·4 for greasy belts. By using the following table the right hand member of equation (1) can easily be found for the different arcs of contact $\alpha$.

| | $\alpha$ = fraction of circumf. | $e^{\mu\alpha}$ | | $\frac{e^{\mu\alpha}}{e^{\mu\alpha}-1}$ | |
|---|---|---|---|---|---|
| | | $\mu = 0{\cdot}3$ | $\mu = 0{\cdot}4$ | $\mu = 0{\cdot}3$ | $\mu = 0{\cdot}4$ |
| 90° | 0·250 | 1·60 | 1·87 | 2·66 | 2·15 |
| 120° | 0·334 | 1·87 | 2·31 | 2·14 | 1·77 |
| 150° | 0·417 | 2·19 | 2·84 | 1·84 | 1·54 |
| 180° | 0·500 | 2·56 | 3·51 | 1·64 | 1·40 |
| 210° | 0·583 | 3·00 | 4·33 | 1·50 | 1·30 |
| 240° | 0·666 | 3·51 | 5·34 | 1·40 | 1·23 |

Let, now, an endless belt be strained over two pulleys, and suppose that it is required to transmit N horse-power with a pulley of D inches diameter and $n$ revolutions per minute, we get the resistance at the circumference of the pulley to $P = \frac{12 \times 33000N}{D\,\pi\,n} = 126000 \frac{N}{D\,n}$.

To cause motion of the pulleys it is necessary that the difference of the belt's tensions T and $t$ is equal to the resistance P of the pulley acting on the circumference. We have, therefore, $T - t = P$, and from equation (1), the value for $t$, $T - \frac{T}{e^{\mu\alpha}} = 126000 \frac{N}{D\,n}$, or the greater tension in the driving belt is

$$T = 126000 \frac{N}{D\,n} \left(\frac{e^{\mu\alpha}}{e^{\mu\alpha}-1}\right) \quad \ldots \quad (2).$$

According to Unwin, Mach. Design, the strength of leather used for belting varies from 3,000 to 5,000lb. per square inch, and is reduced in laced joints from 900lb. to 1,500lb., and by using a safety co-efficient of *ca.* 3 we get the safe working tension in a belt to 320lb. per square inch. The thickness of belts varies in general with the width $w$, and is from $\frac{3}{16}$ to $\frac{3}{4}$in. The price of leather belts depends on the weight, and it is therefore reasonable to construct the formula for calculating the width of belts in such a way that a thicker belt requires a smaller width, and the thinner a greater width. Of course the elasticity of belts is diminished with the thickness, and the result of the above derivation of the theory of a perfect elastic band would require some correction, the omission of which only increases the working tension to not more than 10 per cent., which may be allowed.

Putting, now, the section of the belt equal the working tension T we have

$$320\,w\,\delta = 126000 \frac{N}{D\,n} \left(\frac{e^{\mu\alpha}}{e^{\mu\alpha}-1}\right)$$
$$w\,\delta = 400 \frac{N}{D\,n} \left(\frac{e^{\mu\alpha}}{e^{\mu\alpha}-1}\right) \quad \ldots \quad (3).$$

The value of the factor within the brackets can be easily taken from the given table. The number 2 is often used for rough calculation, taking the embrace of the pulley to 0·4, thus giving us the following formula, which can be easily remembered:—

$$w\,\delta = 800 \frac{N}{D\,n},$$

all dimensions in inches.

To see how the results of this formula harmonise with

Digitized by Google

practice let us calculate the width of the belt for the dynamo described on page 547, Vol. XI. The horse-power to be consumed by the dynamo amounts to 25 horse-power, the number of revolutions is 500, diameter of pulley 14in., then we have

$$w\,\delta = \frac{25 \times 800}{14 \times 500} = 2{\cdot}85,$$

and assuming $\frac{3}{8}$in. thickness of belt we get the width to

$$w = 7{\cdot}6 \text{ to } 8\text{in.},$$

which corresponds with the construction. The width of the pulley is given to 9in.

The force acting on the circumference of the pulley is

$$P = \frac{126000 \times 25}{14 \times 500} = 450\text{lb.}$$

The tension of the driving belt is

$$T = \frac{126000 \times 25}{14 \times 500} \times 2 = 900\text{lb.},$$

the tension of the driven belt

$$t = \frac{T}{e^{\mu a}} = \frac{900}{2} = 450\text{lb.},$$

the tension of the belt during repose is

$$\frac{T + t}{2} = \frac{900 + 450}{2} = 675\text{lb.}$$

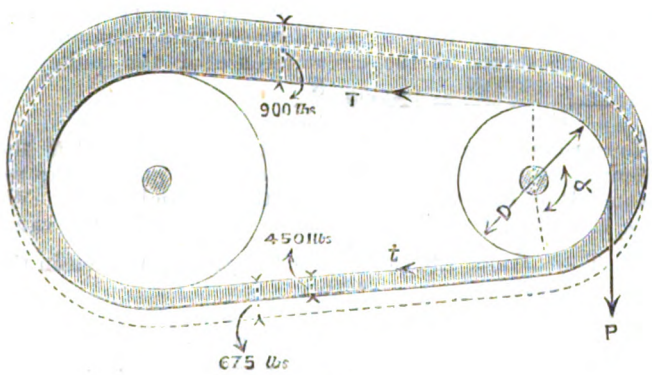

FIG. 3.

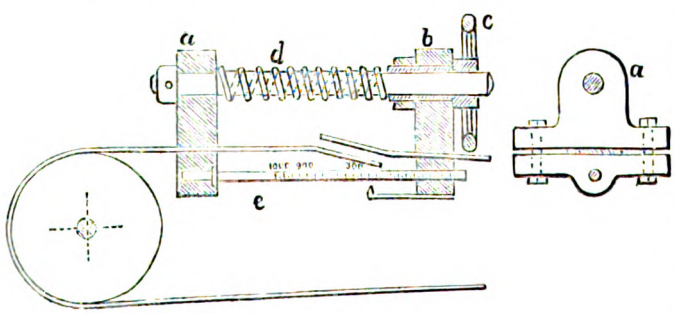
In Fig. 3 are represented the different strains of the belt, the length of the perpendiculars erected on the belt show how the change of the strain during motion takes place. The dotted line gives the strain during repose. We see from the diagram that the change of the strain in the different parts of the belt cannot take place without any slip. For practical purposes it may be added that the slip of such a belt is approximately not more than $2\frac{1}{2}$ per cent.



FIGS. 4 and 5.—Belt Straining Machine.

The answer to the question, With what force is it necessary to strain a belt when put over the pulleys to be laced together? is the strain during repose, viz., $\frac{T+t}{2}$, in the present case 675lb. Not according to the usual way, it may be here recommended to use the following mechanical arrangement of straining the belt before laced together. Figs. 4 and 5 explain themselves. By turning the wheel *c* the two brackets *a* and *b* screwed on the belt will approach each other and compress the spring *d*, the pressure of which can be read off from the scale *e*. As soon as the belt has the required tension, the two ends can be easily laced together. A few words may be added concerning the velocity of belts, which, after Roper, may be taken to be not more than one mile per minute; and it is the author's idea that by using a great belt velocity the centrifugal force of the belt will perfectly compensate the action of a vacuum between belt and pulley. The diameter of pulleys is, as a rule, not to be made smaller than the width of it.

## CORRESPONDENCE.

### DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The query under this head can only be answered with certainty by some one acquainted with the ordinary construction of the type in question. But I beg to offer some remarks from a more general point of view.

There are two main conditions which must be satisfied by any dynamo.

1. The coils of the field magnets must be sufficient to magnetise the cores to saturation, or nearly so, when working under the circumstances intended.

2. The coils of the armature must be sufficient to develop the E.M.F. required, at the intended speed, when the magnets are saturated.

It does not always follow that the machine will start itself; but if these conditions are not satisfied the machine cannot maintain its action.

In my judgment neither of the above conditions are properly satisfied by the arrangement in question, so far as I can judge from the slight description given.

The number of ampere turns required to excite the magnets in my A Gramme machine is somewhat over 20,000 for the four magnets.*

I have inquired often about this constant in other machines, but have received very little information. In large machines I have found it two or three times as great. I judge that for the machine in question it may possibly be as low as about half the quantity for my Gramme machine, *i.e.*, 10,000 altogether, or 2,500 for each magnet.

Now, if V be the number of volts between the brushes, and we suppose the machine short circuited through the main coils, the number of ampere turns in one magnet will be†

$$V\left(\frac{50}{\cdot 5} + \frac{280}{9}\right) = 131\ V \text{ nearly.}$$

Equating this to 2,500 we find V = 19 nearly. But the current in the main circuit would be 38 amperes, and the wire would not carry this for long.

If we put half an ohm into the external circuit, we have

$$V\left(50 + \frac{280}{9}\right) = 81\ V \text{ nearly,}$$

and V must be 31 nearly. Here the wire of the shunt begins to be overloaded, while the main wire still has more than it will carry. On the whole, then, the excitation can be maintained with small external resistance if moderate E.M.F. can be developed; but the wires will hardly bear the necessary currents for any time. A much greater number of coils would be desirable.

Now to examine the action of the armature. To obtain

* For the evidence that the magnets are nearly saturated under these conditions, see *Phil. Mag.* XV., 285.

† The data are (p. 607), main circuit on field magnets = ·5 ohm, 50 turns on each leg (single magnet?). Shunt circuit 9 ohms, 280 turns on each leg (?). Armature = ·4 ohm, 84 turns. Armature and main circuit 16 B.W.G. Shunt circuit 22 B.W.G.

Digitized by Google

some idea of the efficiency of the magnetism I will first consider my Gramme machine.

$A$ = area of magnet core.
$n$ = number of coils in the Gramme ring.
$\frac{1}{\tau}$ = number of revolutions per second.
$V$ = number of volts (total).
$\phi$ the proportion of the lines of force which are efficient (*i.e.*, cut the coils).
17000 = number of lines of force per unit area for saturated soft iron.

Then $$\phi A . \frac{2n}{\tau} 17000 = V . 10^8.$$

(For the 17000 $\phi$ A lines of force cut each of the $n$ coils 4 times in each of the $\frac{1}{\tau}$ revolutions; and these cuttings are distributed over the two halves of the armature.)

I take the conditions as when driving an arc light.

$A = 45{\cdot}6$ sq. cm.
$n = 1700$. (This is the number given. But it seems hardly possible to get this number into the ring.)
$\frac{1}{\tau} = 15$ (900 per minute.)
$V = 60$.

Putting these into the above expression we find for the efficiency of the magnetism ($\phi$) 15 per cent. nearly.

In a larger incandescent machine which I have examined I find 28 per cent.

We may conclude provisionally that the efficiency is not likely to be higher than about 1 in 5.

There are no data for the section of the magnet cores of the machine now in question. For a rough guess, I will assume that it is 20 sq. cm. in each magnet.

In a Siemens machine, all the efficient lines of force pass twice through the coils of the armature in each revolution, and the E.M.F. is that of half the coils.

$$\therefore 17000\, \phi\, A \frac{2n}{\tau} = V\, 10^8.$$

I will put $\phi$ (efficiency) $= \frac{1}{5}$, $n = 84$, $\frac{1}{\tau} = 20$ (1200 per minute). Whence we find $V = 2{\cdot}28$ volts nearly, if the magnets are saturated.

But we require 19 volts between the brushes to maintain the excitation, even if there is no external resistance.

If my guesses at the quantities concerned are at all correct, the armature is insufficient for the purpose. The number of coils on the armature ought to be, say, 20 times as great; more like 1,600 than 80.

This case illustrates the general truth that small models of dynamos, or of any other machines involving the use of nearly saturated electro-magnets, or of moving coils, cannot always be made to work. For the number of current turns required for magnetising does not diminish very rapidly with the dimensions. The number of turns in a moving coil cannot be diminished at all, and only remains the same if we suppose the velocity to vary inversely as the square of the linear dimension. And the currents remaining the same, the diameter of the wire cannot be diminished. So that the space occupied by coils cannot generally be materially diminished.—Yours, &c.,

R. H. M. B.

## COMPARING THE E.M.F. OF BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I see in your issue of November 17, page 9, in the directions for comparing the E.M.F.'s of batteries by means of the condenser, the recommendation often given to use a shunt to make the kick of the galvonometer the same in both cases. It is assumed that the quantities of electricity going through the galvanometer and shunt respectively are in the same ratio for the momentary currents from the discharge of the condenser as in the stable condition of constant currents. Now this is never the case, because of the retardation due to self-induction in the respective coils. It would be almost impossible to make the ratio of these retardations the same as the shunt ratio if coils were wound with that special object, and in the coils that must be used as shunts the self-induction is made as small as possible, while in the galvanometer coil it must necessarily be considerable. As a consequence a much larger proportion of the current goes through the shunt when a condenser is discharged than when a permanent current is flowing.

A plan giving much better results, according to my experience, is to connect the poles of the battery by a conductor of very high resistance, then find points upon this conductor which, when connected with the plates of the condenser, communicate a convenient charge with battery A, then find other points which communicate the same charge with battery B. If R = entire resistance, $r$ and $r$ resistance between poles of condenser in each case, $e$ = difference of potential between poles of condenser, then

$$\frac{\text{E.M.F. of A}}{\text{E.M.F. of B}} = \frac{\frac{R}{r}}{\frac{R}{r'}}_e = \frac{r'}{r}.$$

Another way is to use a divided condenser, charge one section of this, and then subdivide the charge among the other sections in such a way that what remains shall give a convenient deflection, and the same deflection for each battery. To obtain good results when high potentials are used it is necessary to take care to eliminate, or allow for the penetration of the charge into the dielectric.—Yours, &c.,

WM. A. ANTHONY.

The Cornell University, Ithaca, N.Y., Dec. 9, 1883.

## DYNAMOMETERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the very interesting series of articles on mechanical dynamometers appearing in your columns by Mr. Kapp, reference is made on page 104 to our "compensating dynamometer," and it is stated that its principle is similar to that of a pulley over which passes a band attached at one end to a spring balance and carrying a weight at its other. May we be permitted to remark that this idea is a mistaken one? Such a dynamometer as the one just referred to is compensating undoubtedly, but its compensation is produced by a change in the difference of the pulls on the two sides of the pulley, or, in other words, by a *change* in the load. Now, such a method of automatic compensation is quite useless for a great number of purposes, as, for example, when it is desired to measure the efficiency of an electro-motor and the amount of current necessary to be employed when the motor is running at different speeds with a *constant* load. The compensation in our dynanometer is produced by no change in the actual pulls on either side, nor, as in the case of the dynamometers of Professor J. Thomson, of Messrs. Carpentier, Raffard, &c., by a more or less complicated variation of the amount of cord wrapped on. But the mere employment of a knot of particular construction, used to join a thick and a thin cord, enables the apparatus to perfectly compensate itself without adjustment for changes in the co-efficient of friction, so that the speed at which the machine is being driven is the only thing that can vary for any given weights put into the two scale pans.—Yours, &c.,

Dec. 24, 1883. AYRTON AND PERRY.

## MAGNETO-ELECTRIC INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue I read with much interest the reply of Mr. D. G. FitzGerald on the above subject. I have studied the Gramme machine, but have failed as yet to find any satisfactory explanation of its action. If Mr. FitzGerald would kindly explain it, with the necessary diagrams, I feel sure that it would be a subject of interest to many others of your readers, who, like myself, are in doubt on this point.—Yours, &c.,

S. THORNTON.

## *ANSWER TO CORRESPONDENT.*

STUDENTS' COLUMNS.—M. J. M. WILLIAMS.—*We are glad you derived benefit from these columns, and hope that you were not alone in this respect. The answers to examination papers which we published a short time since were an experiment so far as we were concerned. We shall be glad to know whether other students appreciated them, and to hear from them on the subject. If there is a general concensus of opinion in favour of their resumption, we will do our best to meet the demand.*

## SCIENCE AND ART.

The notice which Sir Charles Dilke's remarks on Science and Art have attracted is due, perhaps, more to the man and the occasion than to any special novelty or heresy in what he is reported to have said. Few people imagined that the busy politician who represents the Borough of Chelsea felt any solicitude for Art, and nobody expected that at a distribution of prizes to students of Science and Art he would deliberately assign a second place to the study which other people usually put first. That Sir Charles Dilke had the courage to speak his mind was to be expected of him, but that such is his mind is certainly noteworthy in these days, when the tyranny of a phrase or an epithet is all but irresistible. When South Kensington established its Science and Art curriculum it authoritatively proclaimed the precedence of Science, and until now its decision has remained paramount and unchallenged. But in reality the dictum was wrong from the beginning, both historically and ethically; and Sir Charles Dilke has done no harm, but, rather, good, in drawing attention to the mistake.

The best proof that a reminder on this point was needed is the irritation it has occasioned in certain quarters. With this irritation we have not the least sympathy. If any public man thinks with Goethe—and we may add with the wisest of all ages—that the useful can take care of itself, but that the beautiful must be cared for, he is entitled to say so, and we do not see why the makers of useful things need be angry about it. In point of fact they are not angry; they have more good sense than to feel annoyed at a bare statement of fact which in no way reflects on their useful work. It is reserved for the votaries of Science to exhibit to the world a touchiness which is neither dignified nor expedient. Dr. Ray Lankester, who lately claimed for himself the right to advocate the endowment of Science, hastens to let the world see how the hierarchs of Science would use their powers if they had it all their own way. Surely we might allow those to whom Art has greater charms than Science to indulge their fancy without accusing them of retarding civilisation. If Dr. Lankester has many followers in the scientific world who fancy that on Science and Science alone the progress of civilisation depends—as would seem to be implied in his letter to the *Pall Mall Gazette*—all we can say is that it would be best to keep the fancy to themselves, for it is more likely to defeat than to further the aims which underlie it. The assertion of it will assuredly be treated as an impertinence, and the men who put it forward as ill informed—or imperfectly formed—bigots. Science is good, and Art is good; but there are other things besides and beyond either or both of these on which the world's advancement depends, and without which scientific progress, necessary and valuable though it be, would leave us in but a poor plight. Sir Charles Dilke spoke of Science in these days running riot about us; if anything would justify such hard language it is the extravagant and one-sided assumptions of his critics.

The democratic orator of Chelsea told the Science and Art students that for his part he was inclined to think that Art nowadays needed more care and attention at the hands of the community generally than did Science. This is purely a question of fact; but Dr. Lankester perverts it into a declaration of principle, namely, that Art ought to be encouraged and Science discouraged. Nothing of the kind was said; but even if it had been said it is a matter for argument not for scolding. The search for knowledge, says Dr. Lankester, "never has taken care of itself and never can do so." If by taking care of itself he means that the searchers did not take care of number one we quite agree with him; but the illustrious names he cites are proofs, if any were needed, that the most successful pursuit of Science has been achieved by men who neither cared for themselves nor were cared for in any special or exceptional manner. It is one of the marks of a truly scientific mind that it takes note of all the facts. Dr. Lankester is unmindful of many facts, known pretty generally to the rest of the world, that what is true of the ill-rewarded scientists—all honour to them—is equally true of Art, of Letters, and of Religion, to say nothing of warfare and travel. We could have wished that a representative scientific critic had been a little more scientific in his survey of facts.

One passage in Sir Charles Dilke's speech clearly pointed to the reckless disregard of Art and of the beautiful shown in recent years by the products of Science. He mentioned the telephone, a most beautiful and artistic instrument in itself, but one which undeniably has conduced more to the disfigure-

Digitized by Google

ment of our public thoroughfares in a couple of years than the worst class of architecture could have accomplished in a generation. This fact was probably in the artistic democrat's mind when he spoke disparagingly of the telephone. His critic might learn the lesson that the world is not likely ever to draw the distinction he seeks to establish between scientists and inventors. By scientists Dr. Lankester always means searchers in physical science; that being so, we fail to see the logic of his falling foul of "great inventors, electricians, and others" who reap all the pecuniary fruits of scientific discoverers, but never pay them anything in return. This is ungrateful; and as an appeal to inventors to endow research the plea is as good as one of the same kind addressed to a lion by the jackal. But Dr. Lankester cannot escape the consequences of discovery by simply asserting that "Science" and "invention" are two different things. Taking him on his own ground, what, we ask, would be the use of research if it were not applied to the wants of mankind? The progress about which he talks so much implies the application of discoveries to practical purposes; and it is not to be wondered at that ordinary mortals, who have no partiality for endowments, but care very much for what Sir Charles Dilke calls moral and intellectual pleasures, hold Science responsible for what Science has assuredly led to. If Dr. Lankester means—though we can hardly think he does mean it—that scientific research should not be followed by, and is not responsible for, its practical and sometimes vulgar application, he ought to say so, and he should then join hands with the member for Chelsea. Further, if by his reference to inventors who make fortunes "aided by our Patent Laws" Dr. Lankester means that patent laws ought not to exist, he should say as much in plain words. Here, again, the democratic leanings of his opponent might incline in the same direction. But in that case, alas! there would be no endowment for research, no subsidising of scientists, which is what Dr. Lankester is understood to be aiming at, but which, in fact, amounts to asking that there shall be Letters Patent for Science and for nothing but Science. It is such pretensions as these that provoke, and justly so, the attacks of the non-scientific world.

## ON A MAGNETIC BALANCE, AND EXPERIMENTAL RESEARCHES MADE THEREWITH.*

BY PROFESSOR D. E. HUGHES, F.R.S.

In a paper "On the Molecular Rigidity of Tempered Steel,"† I advanced the theory that the molecules of soft iron were comparatively free as regards motion amongst themselves, whilst in hard iron or steel they were extremely rigid in their relative positions.

I have since widened the field of inquiry by observing the effects of mechanical compression and strains, as well as annealing and tempering, upon the magnetic capacity of sixty varieties of iron and steel, ranging from the softest Swedish iron to the hardest tempered cast steel.

We know already that soft iron will take a higher degree of temporary magnetism than steel, and that tempered steel retains magnetism more than soft iron; consequently, we might believe that by the aid of an instrument which should give correct measurements, we might be able to include all varieties of iron and steel between the two extremes of softness, as in annealed iron, and hardness, as in high-tempered cast steel. This proved, however, not to be the case, if the iron and steel were not all annealed to one absolute standard, and if magnetised to or near saturation.

In a late paper upon theory of magnetism,* I said:—

"During these researches I have remarked a peculiar property of magetism, viz., that not only can the molecules be rotated through any degree of arc to its maximum, or saturation, but that, whilst it requires a comparatively strong force to overcome its rigidity or resistance to rotation, it has a small field of its own through which it can move with excessive freedom, trembling, vibrating, or rotating through a small degree with infinitely less force than would be required to rotate it permanently on either side. This property is so marked and general that we can observe it without any special iron or apparatus."

In order to observe this in electro-magnets, we must employ an extremely feeble current, such as from one Daniell cell, with an exterior resistance of from 10 to 1,000 ohms, and we then find the following laws hold with every variety of iron and steel:—

1st. That its magnetic capacity is directly as its softness or molecular freedom.

2nd. That its resistance to a feeble external magnetising force is directly as its hardness, or its molecular rigidity.

This has proved to be the case upon sixty varieties of iron and steel furnished me direct from the manufacturers, and it was remarked that each variety of iron or steel has a certain point beyond which annealing cannot soften, nor temper harden; consequently, if all varieties were equally and perfectly annealed, each variety would have its own magnetic capacity; or its specific degree of value when perfectly annealed or tempered, by means of which, we could at once determine its place and quality.

If in place of several varieties we take a single specimen, say hard-drawn Swedish iron wire, and note its magnetic capacity, we find that its value rises rapidly with each partial annealing, until an ultimate softness is obtained, being the limit of its molecular freedom. We are thus enabled to study the best methods of annealing, and to find at once the degree of softness in an unknown specimen. A similar effect occurs in observations upon tempering, from the softest to the hardest temper, until we arrive at its ultimate molecular rigidity.

We have thus in each piece of iron or steel a limit of softness and hardness. In soft Swedish iron tempering hardens but 25 per cent., whilst mechanical compression (such as hammering) hardens it 50 per cent. In cast steel tempering hardens it 400 per cent., whilst mechanical compression gives but 50 per cent. Between cast steel and Swedish iron we find a long series of mild steel and hard iron, varying in their proportionate degree between the two extremes mentioned.

In order to carry out these researches, I constructed an instrument which I have called the magnetic balance. It consists of a delicate silk-fibre suspended magnetic needle, 5 centims. in length, its pointer resting near an index having a single fine black line or mark for its zero, the movement of the needle on either side of zero being limited to 5 millims. by means of two ivory stops, or projections. When the north end of the needle and its index zero are north, the needle rests at its index zero, but the slightest external influence, such as a piece of iron 1 millim. in diameter 10 centims. distant, deflects the needle to the right or left according to the polarity of its magnetism, and with a force proportional to its power. If we place on the opposite side of the needle at the same distance a wire possessing similar polarity and force, the two are equal, and the needle returns to zero, and if we know the magnetic value required to produce a balance we know the value of both. In order to balance any wire or piece of iron placed in a position east and west, a magnetic compensator is used, consisting of a powerful bar magnet free to revolve upon a central pivot, placed at a distance of 30 or more centims., so as to be able to obtain delicate observations.

* Paper read before the Royal Society, December, 1883.

This turns upon an index, the degrees of which are marked for equal degrees of magnetic action upon the needle.

A coil of insulated wire, through which a feeble electric current is passing, magnetises the piece of iron under observation, but as the coil itself would act upon the needle, this is balanced by an equal and opposing coil on the opposite side, and we are thus enabled to observe the magnetism due to the iron alone. A reversing key, resistance coils, and a Daniel cell are required. Great care must be taken so that the electromotive force remains a constant, as a small variation in the electromotive force gives large variations in the readings, and many important details of construction are required in order that it shall give perfect readings for extremely small magnetic force. Still greater care is required that each specimen of iron or steel shall be annealed to its maximum.

Several methods of observation have been employed with the magnetic balance, the usual one being the one described, but interesting results are attained by observing the influence of earth's magnetism alone on the iron or steel, or we may magnetise all specimens to the same value, and note the amount of current required. We may observe the remaining magnetism after the cessation of the current, or the influence of a weak current after the passage of a strong magnetising force. These are more applicable to researches upon the cause of magnetism.

By means of this instrument I have tested sixty varieties of iron and steel, mostly in the form of wires, a wire 1 millim. diameter, 10 centims. long, being the standard used. In all comparative experiments we require one standard form, to which all the rest must be similar in form and size; at present, we cannot readily compare a square or flat bar with a piece of wire, but if all pieces have the same form, and all are annealed to the same standard, then any difference observed between them must be due to their comparative softness, from which we can deduce its quality and place on the line from soft iron to cast steel.

Annealing not only produces softness and consequent molecular freedom, but it entirely frees it from all strains previously introduced by drawing or hammering. Thus a bar of iron drawn or hammered has a peculiar structure, say a fibrous one, which gives a greater mechanical strength in one direction than another. This bar, if thoroughly annealed at high temperatures, becomes homogeneous, and has no longer even traces of its previous strains, provided that there has been no actual mechanical separation into a distinct series of fibres.

TABLE I.

Influence of annealing upon Swedish iron, sample G.
Degrees of softness indicated upon the magnetic balance:—

| | | |
|---|---|---|
| Wire, hard drawn, as furnished by the makers, | | 230deg. |
| Annealed at black heat | | 255 „ |
| „ | dull red | 329 „ |
| „ | bright red | 438 „ |
| „ | yellow | 507 „ |
| „ | yellow-white | 525 „ |

From the above table, we notice that a regular increase of softness occurs as the temperature at which it is annealed increases, the maximum being at a point under that of fusion.

Numerous methods of annealing were tried, the highest results being obtained when the iron or steel was heated as rapidly as possible to a high temperature, and cooled in a neutral surrounding or atmosphere. The facts regarding annealing as pointed out by the measurement of the magnetic capacity of iron have, no doubt, been in great measure perceived by ordinary mechanical methods; the results of my own researches may be thus formulated:—

1. The highest degree of softness in any variety of iron or steel is that obtained by a rapid heating to the highest temperature less than fusion.

2. The time of gradual cooling required varies directly as the amount of carbon alloy.

Thus, in chemically pure iron rapid cooling, as in tempering, would not harden it, whilst steel might require several days, even for pieces only 1 millim. diameter. Slow cooling has no injurious effect upon pure iron when cooled in a neutral surrounding; consequently, where time is no object, we may employ slow cooling in every case.

A wire or piece of iron, thoroughly annealed, must not be bent, stretched, hammered, or filed, as the hardening effects of a bend are most remarkable, and the mere cleaning of its surface by sand paper hardens its surface several degrees.

The following table shows the effect of annealing upon a series of wires, kindly furnished me expressly for these experiments by Messrs. Frederick Smith and Co., of Halifax:—

TABLE II.

| Marked. | —— | Magnetic capacity. | |
|---|---|---|---|
| | | Bright hard drawn. | Annealed. |
| G | Best Swedish charcoal iron, 1st variety | 230 | 525 |
| F | Best Swedish charcoal iron, 2nd variety | 236 | 510 |
| T | Best Swedish charcoal iron, 3rd variety | 275 | 503 |
| S | Swed'h Siemens-Martin iron | 165 | 430 |
| H | Puddled iron, best best | 212 | 340 |
| Y' | Bessemer soft steel | 150 | 291 |
| Y | Bessemer hard steel | 115 | 172 |
| Z | Crucible fine cast steel | 50 | 84 |

The above series contains representative irons and steel of all classes; all other varieties yet tried stand between cast steel and Swedish iron (generally classed as hard cast steel) hard steel, mild steel, hard puddled iron, soft iron, Swedish charcoal iron.

From the above table it will be seen that every wire rises greatly in value by annealing, and that we could not estimate the true magnetic capacity of any iron or steel unless special attention was given that all should be annealed to their maximum.

The influence of tempering upon the magnetic retentivity or molecular rigidity has been shown in every piece of iron or steel examined, the molecular rigidity of tempered cast steel being proportional to its species of temper as shown in Table III.

TABLE III.

| | Magnetic capacity. |
|---|---|
| Crucible fine cast steel, tempered. | |
| Bright yellow heat cooled in cold water | 28 |
| Yellow red „ „ | 32 |
| Bright yellow tempered in cold water let down to straw colour | 33 |
| Bright yellow tempered in cold water let down to blue | 43 |
| Bright yellow tempered in oil | 51 |
| Bright yellow tempered in water let down to white | 58 |
| Red heat tempered in water | 66 |
| Red heat tempered in oil | 72 |
| Crucible cast steel annealed | 84 |
| Swedish charcoal iron annealed | 525 |

Table IV. gives the complete results of the mechanical, chemical, and physical tests upon a series of wires furnished by Messrs. Frederick Smith and Co., of Halifax.

The tensile strength and electric conductivity are those furnished me by Messrs. Smith and Co.; the chemical analyses by Mr. Henry S. Bell, of Sheffield. The magnetic capacity of the bright hard drawn, annealed, and tempered wires were determined by myself by the aid of the magnetic balance.

In the following Table IV. there is a complete relation between electric conductivity and magnetic capacity, both progressing in a similar ratio and agreeing in a most remarkable manner.

| S | Swedish Siemens-Martin iron ..... | 226·32 | 34 | 165 | 430 | 390 | 0·10 | trace | 0·035 | 0·034 | 0·324 | trace | 99·60 |
| H | Puddled iron, best best..... | 259·92 | 30 | 212 | 340 | 328 | 0·10 | 0·09 | 0·03 | 0·218 | 0·234 | 0·015 | 99·11 |
| Y′ | Best homogeneous soft Bessemer steel | 266·52 | 35 | 150 | 291 | 255 | 0·15 | 0·018 | 0·092 | 0·077 | 0·72 | trace | 98·74 |
| Y | „ hard „ | 312·69 | 50 | 115 | 172 | 60 | 0·44 | 0·028 | 0·126 | 0·103 | 1·296 | trace | 98·20 |
| Z | Fine crucible cast steel..... | 350·08 | 55 | 50 | 84 | 28 | 0·62 | 0·06 | 0·074 | 0·051 | 1·584 | trace | 97·41 |

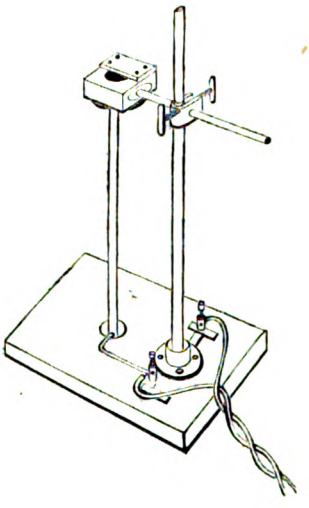
We see here that the electric conductivity and magnetic capacity have a complete relation to each other, but whilst in every wire measured I have found this true, it is only so when the wire has been completely annealed and free from mechanical strain, and a feeble magnetic force employed. Thus the relation exists only in the limited sphere of elastic rotation already mentioned.

I believe that the relation here shown between electric conductivity and magnetic capacity to be of importance in theoretical considerations, and of some practical utility, as we can at once find the electric conductivity of iron and steel from a simple reading of its magnetic capacity, and also show the iron most suitable for the cores of electro-magnets.

## APPARATUS FOR TESTING CARBONS.

The annexed woodcut illustrates an instrument designed and made by Messrs. Brunton and Wilder of the Arc Works, Chelmsford, with a view to facilitate the resistance tests of electric light carbons.

The usual way of fastening clips to the ends of the carbon pencils is open to the objection of variable contact, and some uncertainty as to the exact length of carbon between the clips. Apart from this, too much time is necessary for adjusting the clips and measuring their distance in each case. In the present instrument the contact is by mercury, one cup being in the base plate, the other in a box, which, by means of a sleeve and thumb nut, can be fastened at any height on the vertical brass rod shown in the illustration. This box has a circular hole right through it, and the opening thus formed is closed at the bottom by a rubber disc, having a hole just large enough to admit the carbon, with a sufficiently tight fit to prevent mercury from leaking through. The circular opening on the top of the box is half closed by a little board or lip screwed across, which arrangement prevents the mercury from being spilled if the box be turned or set on edge. In this position the face of the rubber disc is vertical, and the mercury which fills rather less than half of the cylindrical cavity cannot escape by the hole in the disc nor over the lip. If now a carbon is inserted and the box turned through 90°, so that the rubber disc comes to be underneath, the mercury surrounds the end of the carbon pencil, and being itself in electrical connection with the horizontal metal arm of the box and through the stand with one of the binding screws on the base plate, brings that binding screw into electrical connection with the top end of the carbon; the bottom end is in electrical connection with the other binding screw as shown.



The vertical brass rod (made very massive so that variation in the height of the box may not sensibly vary the resistance in circuit) is divided to inches, and thus by the position of the sliding sleeve the length of carbon pencil under test can be read off without need for measuring it.

The connections between binding screws and resistance bridge remain permanently fixed, which allows the testing of a large number of carbons to be done in a comparatively short time.

THE TELEPHONE AT RAMSGATE.—The Ramsgate Improvement Commissioners have established telephonic communication between the police station, gasworks, and waterworks. Bell's telephone and Johnson's transmitter are used, together with H. E. and J. Dale's bells and relays. Mr. William Covington, late of the Post Office, has carried out the work with satisfaction to those concerned.

## THE FISHERIES EXHIBITION.

Perhaps the incandescent light shows to greater advantage amid surroundings of delicate fern leaves, trailing creepers, broken rockwork, and miniature cascades than in any other position. It lends itself to the situation in a manner peculiarly its own, and far surpasses other systems of illumination in this respect. At the recent Fisheries Exhibition Messrs. Dick Radclyffe and Co., exhibited several specimens of ornamental rockwork, combined with ferns, creepers, &c., and amongst them the grotto illustrated in our engraving. This firm have made themselves a name for this kind of work, and have been conspicuous at all the recent exhibitions held in and about London. Of their designs we leave our readers to judge from the example before them. Like the makers of electric light fittings, electroliers, and so forth, the above firm have very soon ascertained that the incandescent lamp is a valuable ally; that it lends itself to combinations which could not possibly be carried out with gas, oil, or even candles and Chinese lanterns. This fact has also come home to the caterers for the amusement of the public, though not, we think, so thoroughly as it ought. That its adoption on a large scale by theatrical managers in all cases where spectacular effect is aimed at is merely a question of time is obvious to all but those who do not wish to see it on the stage or anywhere else.

## LES TÉLÉPHONES.

PAR A. L. TERNANT.

(CONTINUED FROM PAGE 135.)

It is to be remarked that the arrangements of No. 15's jackknife leave the indicator of this subscriber in the shunt circuit of the two line wires (*vide* Fig. 13). This arrangement, will, later on, allow the subscribers to indicate that their conversation has ended by pressing their call button, which will operate the indicator remaining in circuit. This arrangement does not weaken the sounds in the telephone, and we shall see later on that the circuit will admit of two of these shunt circuits without affecting the conversation.

To facilitate the different operations, distinguishing colours have been given to the cords for joining up two subscribers and those for the other connections. The first are green, the others red. In Fig. 11 (p. 135, *ante*) a series of commutators are arranged under the counter. These are jackknives of special form, and are composed of two perforated metal plates separated by a thick piece of ebonite. The whole forms a kind of commutator which allows connections to be made with subscribers in cases where the junction cords mentioned above are not sufficiently long for the purpose, these latter being only 1·50 metre long.

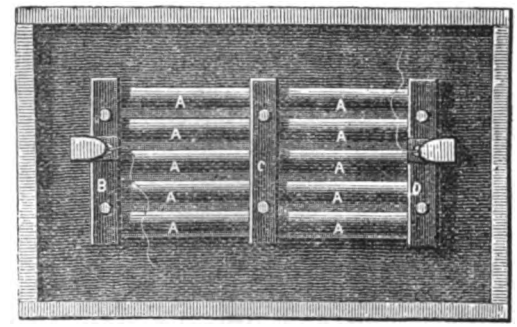

FIG. 16.—The Ader Microphone.

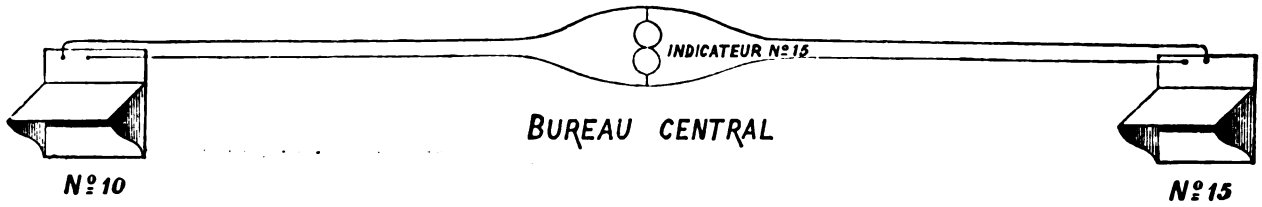

FIG. 13.—Showing Position of Indicators in the Circuit.

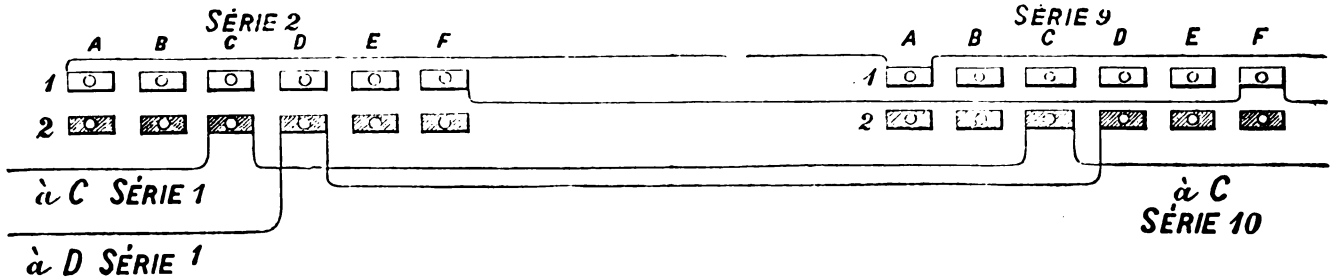

FIG. 14.—Showing the Arrangements of the General Commutator.

FIG. 15.—Connections of Branch Central Offices to Main Central Offices.

Fig. 14 illustrates the connections of the general commutator which between them connect up the series of jackknives. All the jackknives A, B, C, &c., of 1, and A, B, C, &c., of 2 are connected together as a whole by wires from one end of the office to the other, as shown by A and F of 1, and C and D of 2. So that, taking the extreme case in which subscriber No 1 of the first group of 50 (*vide* Fig. 11) wishes to speak with No. 500 of the 10th group, it will be necessary to use the general commutator to connect them, since the ordinary junction cord will not do. Each group of 50 comprising two indicator boards, as shown in Fig. 11, is provided with 60 of these jackknives, but each group may only employ the series of six corresponding according to their row to the number of the group of 50 jackknives comprised in the two indicator boards. The pairs of rows of these jackknives are varnished black, to aid in finding the requisite commutator. Thus, to put No. 1 in connection with No. 500, we take a green flexible cord, one end of which will be inserted in the right-hand hole of No. 1's jackknife, and the other in one of the six jackknives of the first row, say B. We then insert a red cord in the left-hand hole of No. 500's jackknife at the other end of the office, connecting the other plug of this cord with B in the first row of the 10th series of the commutators. These two commutators being connected, a circuit is evidently established. If, on the contrary, No. 500 had asked to speak with No. 1, we should have connected No. 500's jackknife to B in the 10th row of the 10th series, and No. 1's jackknife to B

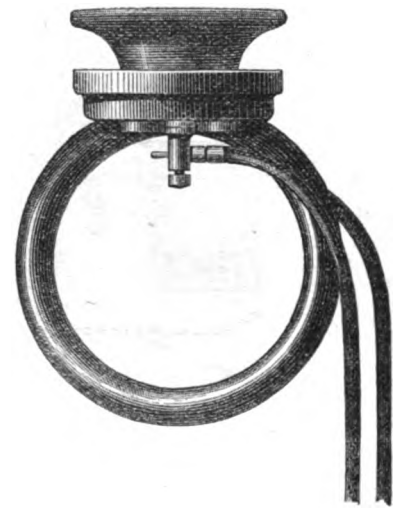

FIG. 17.—General View of Ader Telephone.

Digitized by Google

in the 10th row of the 1st series. In this way it is impossible for two operators to use the connections of the same row of general commutators at the same time.

Besides the central office in the Avenue de l'Opéra, Paris has several other central offices directly connected with one another by means of auxiliary cables. Each of these offices has one or several connections of this kind, which lead directly

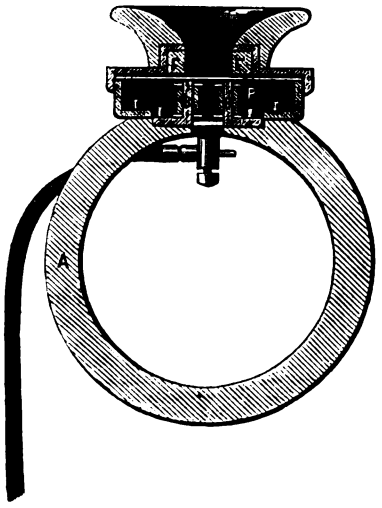

FIG. 18.—Section of Ader Telephone

to a *rosace* situate at No. 27, Avenue de l'Opéra. The connections between the central offices are effected in this *rosace*, and are made by means of paraffin-covered wires, having a number at their ends, as shown in Fig. 15. To establish communication between two subscribers belonging to two different central offices, the operations described above for the principal office are carried out, only in this case the indicators of the two subscribers remain in a shunt from the metallic circuit of the wires. Accordingly the battery current sent to line by each of the subscribers at the end of the conversation causes each one's indicator to fall, whilst during the conversation these shunts do not appreciably diminish the secondary current of the induction coil.

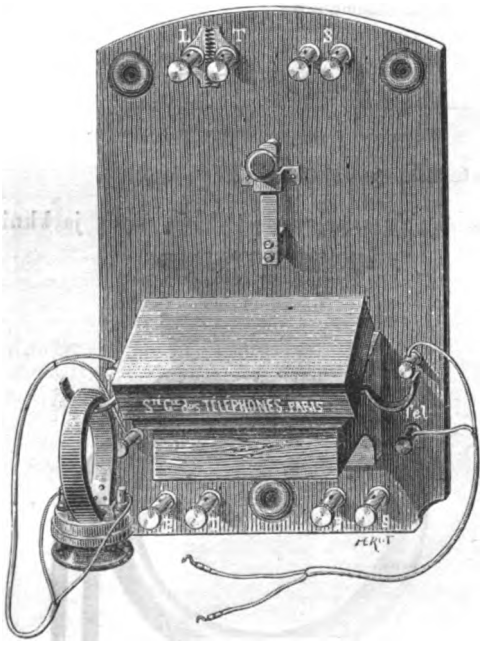

FIG. 19.—Modified Transmitter, used by the Société Générale

The apparatus belongs to and is constructed by the Société Générale des Téléphones. Although it owns the patents for widely differing telephonic and microphonic systems, the société gives preference to the Ader telephone as a receiver, and the Ader microphone as a transmitter. The microphone (Fig. 16) is but a modification of all other microphones. We have two series of carbon rods, A A A A, fixed loosely to three holders, also of carbon, B C D, with the wires attached as indicated. The receiver is shown in Figs. 17 and 18. The section (Fig. 18) shows the parts. A is the magnet, to the poles of which soft iron, B B, is fixed, carrying the coils; P is the vibrating disc, F F is a ring of soft iron, as suggested by M.

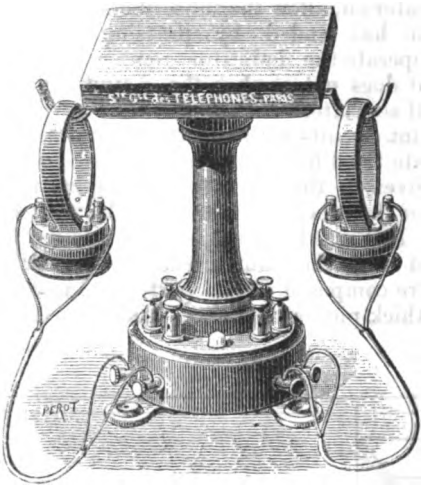

FIG. 20.—New Form of Ader Telephone Transmitter.

Ader. The form of transmitter used till lately is shown in Fig. 19, but this is being replaced by the form shown in Fig. 20.

The author then proceeds to describe the work of Edison, Blake, Hughes, Crossley, with illustrations; thus, Figs. 21 and 22 show the instrument of Crossley, which is largely

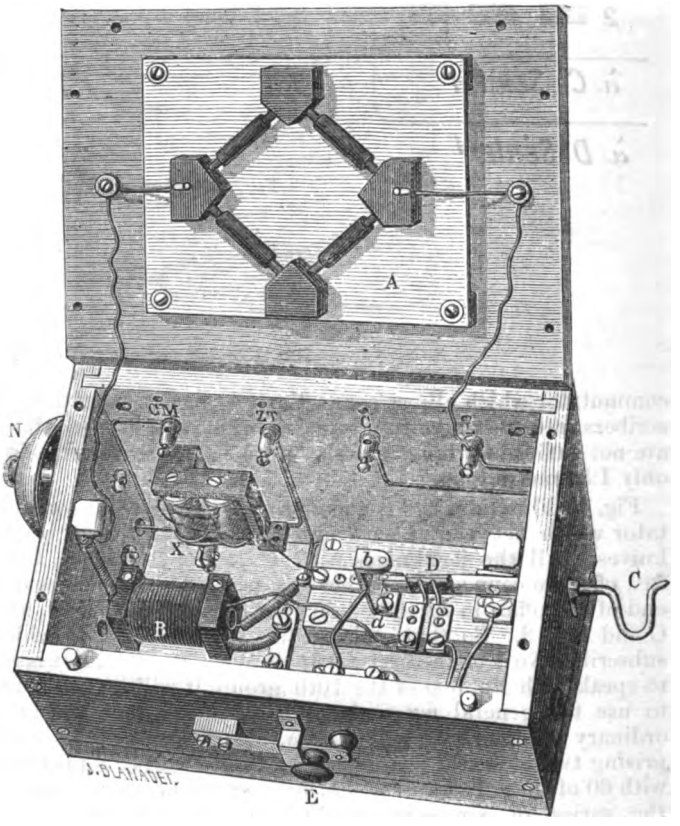

FIG. 22.—Internal View of Crossley Transmitter.

used. From Fig. 22 we see that the lever C D bears against the button A. The point of contact is connected with the key E and to line. Upon the side of C D is a plate of ebonite, and below a piece of copper moving with C D. By this arrangement contact is made between the two little springs shown. The transmitting action is as follows:—Speaking before the disc A, the vibrations are taken up by the micro-

Digitized by Google

phone, which determines the variations in the current of the coil B, the circuit of which is thus constituted, T Z indicates the negative pole, C M the positive. The current goes by primary of coil, the microphone, and the two springs in D.

The receiving currents come by line terminal L, key E, D, *a*, the telephone, secondary wire of coil to T Z. When the telephone is hung on C, contact is broken at *a* and made at *b*, the springs in D slide upon the ebonite and are insulated. To ring the bell, the subscriber presses key E, current arrives by L, key, lever D, *b* coils X to the bell and to earth.

We have merely indicated the manner in which M. Ternant treats this part of the subject, translating literally in some parts and abstracting in others. He gives some interesting figures concerning telephony in Paris, stating 11

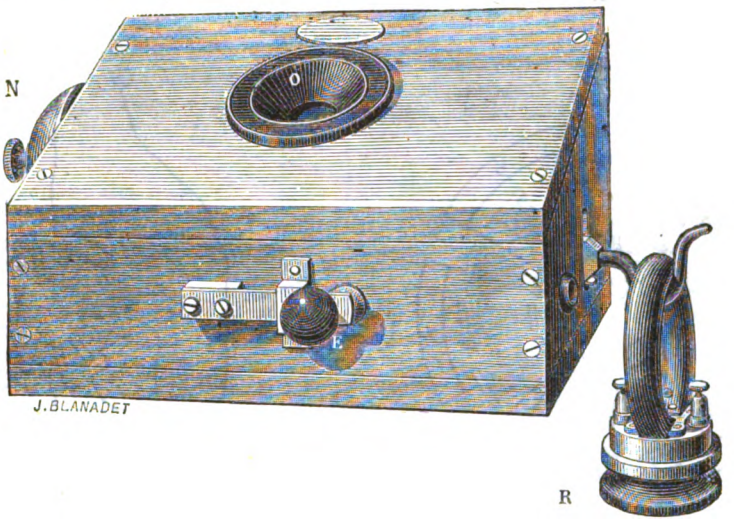

FIG. 21.—Crossley Transmitter. General View.

offices as open and one not yet open. Those opened are designated by letters, the number of subscribers to each being given in the figures in brackets. A (706), B (328), C (193), D (432), E (100), F (71), G (187), H (43), I (62), L (396), M (220), O (not open). The staff consists of the general manager (M. Lartigne), electrician (M. R. J. Brown), engineer (M. Buthon), works manager (M. Gilquin), besides 5 inspectors, 26 linemen, 6 officemen, and 8 men in charge of the batteries, 126 women for daywork, and 39 men for night work. About July last the communications were 150,000 weekly. The following table gives the communications at various provincial towns at the same date:—Lyons (32,246), Marseilles (13,950), Bordeaux (6,310), Nantes (2,565), Havre (5,969), &c. Except in Paris, where the lines are wholly underground, the provincial systems are aerial.

## SUBMARINE MINES.

(CONCLUDED FROM PAGE 115.)

*The Hochhausen Machine.*—This apparatus, the most recently devised of any to be here described, is an ingenious, compact, and serviceable instrument. It weighs eighty-four pounds, and is contained in a box 12in. by 11in. by 12in. in size. It contains (*vide* Fig. 11) six soft iron electromagnets, so secured that the poles lie on two concentric circles and alternate in polarity. The coils of these magnets are united in series, the terminals being connected to two opposite commutator half-plates, which will soon be described. The wire is of copper, of No. 18 B.W.G., with a total resistance of 12·3 ohms, or about 2 ohms to each magnet. The poles project about 2in. beyond their coils.

An axis, central to the magnets, is geared to a crank so as easily to give a speed of about 425 revolutions per minute—3·2 turns of the axis to one of the crank. A circular plate of brass, perpendicular to this axis, is rigidly attached to revolve just in front of the magnetic poles. It carries fourteen soft iron armatures, so placed as to pass close between H to overlap the projecting poles of the magnets. These armatures are each wrapped with 1·1 ohm of copper wire of No. 20 B.W.G. They are coupled by their inner wires, two and two, on diameters of the brass circle, thus forming seven separate circuits, each containing two coils, which must always be approaching and receding from similar magnetic fields at the same time. They are wound so as to send their induced currents in the same direction, thus making each of the seven circuits analogous to two cells coupled in series. The outer wires of the coils are attached to insulated brass segments on the axis, each pair on opposite sides of the axis.

The commutator is a novel feature of the machine. It consists of six insulated metallic plates, placed opposite the intervals between the magnets on a sheet of ebonite, and abutting against springs projecting from the revolving ends of the segments. The first, third, and fifth of these plates are united by a brass strip, and extended to the other post. The width of the plates is sufficient to slightly overlap two adjacent segments, which give currents moving in the same direction, since one is leaving and the other approaching

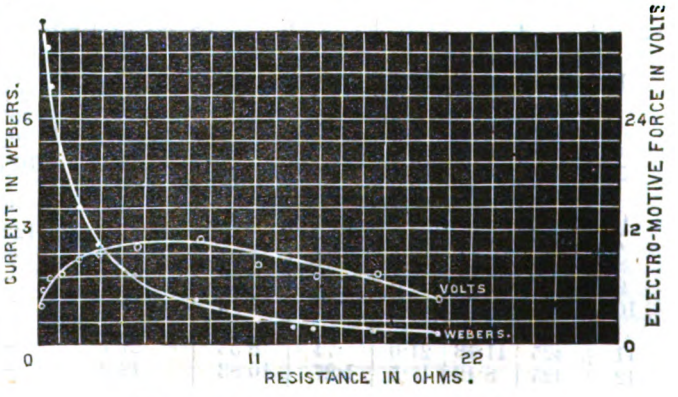

FIG. 12.—Diagram of Hochhausen Machine.

magnets of opposite polarity. To supply the magnetic fields, two of the opposite commutator plates are each cut into two insulated halves, and the current from each of the two coil circuits is thus successively sent at each revolution for an instant through the magnet circuit, which, as already stated, is connected with two of the opposite half-commutator plates. The current drawn off by the other half-plates reinforces the main current as above indicated. Since the different pairs of coils at any given instant are moving in different positions in the magnetic field, some of the induced currents are increasing as others are decreasing. Increased steadiness in

Digitized by Google

the combined current is thus secured. In fine, then, the electrical arrangement is analogous to a battery containing seven groups of two cells each. One group feeds the magnets; and the other six, connected in multiple arc, supply the working current for the exterior circuit.

The method adopted (April, 1876) for testing this instrument was that used with the others of its class, and which has been fully detailed when discussing the Gramme machine (p. 561, vol. XI.). The following table exhibits the results, R′ being ·37ohm. The figures indicate certain peculiarities of the machine which require graphic illustration, and this has been attempted by Fig. 12. By studying these curves in connection with the text following the table, and comparing them with those of Fig. 10, which illustrates the working of the Siemens current machine, a clear idea can be formed of the practical effect of the difference in electrical principles embodied in these apparatus.

This table indicates some curious facts respecting the working of the instrument. As usual, an increase in the speed of rotation of the armature gives an increased current, which implies an increased electromotive force; but no attempt was made to reduce this law to figures, on account of the peculiar changes indicated in the latter quantity as the external resistance was increased, the speed remaining the same.

The condenser measurements show a greater constancy in E than is usually obtained with a Siemens armature, but one far below that given by the Gramme class; but the variation revealed by the first seven observations, when the external circuit was open, proves that very numerous records would be needed to arrive at definite conclusions as to the numerical value of the electromotive force by this plan.

The galvanometer measurements are accordant among themselves, and indicate the usual law of decrease in current as R″ increases. The different values of E given by this

| 24 | 320 | 1·94 | — | 1·98 | — | — | — |

method, however, are peculiar, and not easily explained. They reveal a normal increase as the external resistance increases up to about 8 ohms, when a maximum (about 11 volts) appears to be reached. Beyond this point the electromotive force gradually falls off, until at 20 ohms it is about the same as on short circuit. This anomalous result is confirmed by the condenser seconds, which suggest a very low value for an open exterior circuit, when, by the usual law governing double current machines, it should be high.

The power of the instrument for firing low-tension fuses is the following:—With 425 revolutions of the armature, a single service fuse may be exploded through a resistance of about 15 ohms, and, with the maximum speed, 700 revolutions through 35 ohms. A still further increase of power may be obtained by using a key so arranged as to break an external circuit (about a couple of ohms) when the maximum speed has been secured, and thus to switch the current, reinforced by an extra spark, into the fuse circuit. If fuses in series are to be fired this plan should always be employed, but the machine is hardly suited for such work.

*The Modified Wild Machine.*—This instrument was of quite a different character from any of the preceding, being driven by a steam engine, and designed to supply a current of enormous quantity. It was made by the Laflin and Rand Powder Company, and was tested at their works at Wayne, N.J., in March, 1876. It weighed 900lb., and occupied a space of 34in. by 14in. by 42in. in height. It was claimed that with 4 horse-power about 1,500 revolutions per minute could be given when working on short circuit.

In principle it was identical with the Wild machine; but the permanent magnets were replaced by an electro-magnet actuated by a small Siemens armature, which supplied the current for creating the two independent magnetic fields of force in which it and the working Siemens armature revolved. Both armatures were geared by separate belts to the shafting, and were, of course, quite distinct from each other. The small armature was 10 inches long by 2½ inches

Digitized by Google

in diameter, and was wound with Lake Superior copper wire of No. 12 B.W.G. Its magnet was wound with No. 5, and the main magnet with No. 8 copper wire of the same gauge. The working armature was 20 inches long by 4 inches in diameter, and was wound with 30 pounds of a square copper rod about ·2in. on the edge, and insulated with silk ribbon. Its length was about 190 feet, and its resistance at 54° Fahrenheit was ·0428 ohm. The secret of the power of the machine lay in this excessively small internal resistance, which made its whole energy available for the external circuit.

Wheatstone's method was employed to measure the electromotive force, the standard of comparison being six Daniell cells freshly set up with pure chemicals, and compared with a Clark standard cell by Law's method. Very long leading wires were used to avoid any magnetic disturbance of the needle of the galvanometer, which was a good instrument, having a resistance of about 30 ohms and a well-determined weber co-efficient. The following table exhibits the data thus obtained, and a comparison of the results with the indications of the formula given below:—

OBSERVATIONS WITH THE MODIFIED WILD MACHINE.

| Number of observations | Revolutions per minute (T) | Resistance of circuit (R′ + R″) | Current by galvanometer (C) | Electromotive force (E) | | | | Difference |
|---|---|---|---|---|---|---|---|---|
| | | | | Wheatstone method | c(R′+R″) | Grand mean | Computed E | |
| | | ohms | webers | volts | volts | volts | volts | volts |
| 1 | 1,460 | 2150·9 | ·0183 | 34·24 | 39·36 | 35·46 | 34·97 | +·49 |
| 2 | 1,460 | 5150·9 | ·0066 | | 33·96 | | | |
| 3 | 1,120 | 1550·9 | ·0156 | 28·10 | 24·19 | 26·32 | 26·82 | —·50 |
| 4 | 1,120 | 3150·9 | ·0079 | | 24·89 | | | |

An analysis of the data in the first seven columns of this table proves that, for a large external resistance, this instrument follows the usual law, *i.e.*, for ranges usual in practice, the electromotive force is directly proportional to the speed of revolution of the armature. Its equation appears to be the following:

$$C = \frac{\cdot 02395\,T}{\cdot 043 + R''}.$$

The last two columns show that this equation accords well with the observations. Hence, if the current generated by the small armature be sufficient to maintain a saturated field of force for the working armature when the external resistance is reduced to zero, the machine, at 1,500 revolutions per minute, is capable of yielding under an electromotive force of about 36 volts the enormous current of 835 webers. It is therefore well suited for work requiring great strength of current and comparatively small differences of potential.

---

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 131).

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

### HISTORY IN RELATION TO TELEGRAPHY.

Nor can we give Oersted credit at this period for any more distinct apprehensions. In a work which he published in German, in 1807, on the identity of chemical and electrical forces, he observes† :—

"When a plate composed of several thin layers is electrified, and the layers afterwards separated, each is found to possess an electric polarity, just as each fragment of a magnet possesses a magnetic polarity.

"There is, however, one fact which would appear to be opposed to the theory of the identity of magnetism and electricity. It is that electrified bodies act upon magnetic bodies, as if they [? the magnetic bodies] were endowed with no force in particular. It would be very interesting to science to explain away this difficulty; but the present state of physics will not enable us to do so. It is, meanwhile, only a difficulty, and not a fact absolutely opposed to theory; for we see in frictional electricity and in that of contact [galvanic] analogous phenomena. Thus, we can alter the tension of the electric pile by bringing near it an excited glass rod, and yet not affect in any way the chemical action. A long column of water, or a wetted thread of flax or wool will also suffer a change in its electricity without experiencing any chemical changes.

"It would appear, then, that the forces can be superposed without interfering with each other when they operate under forms of different activities.

"The form of galvanic activity holds a middle place between those of magnetism and [static] electricity. The force is in that form more latent than as electricity, and less so than as magnetism. It is, therefore, probable that the electric force, when superposed, will exercise a less influence on magnetism than on galvanism. In the galvanic pile, it is the electric state [tension] which it acquires that is affected by the approach of an excited glass rod; more, it is not that interior distribution of forces constituting magnetism that we can change by electricity, but it is the electric state which belongs to the magnet as to bodies in general.

"We do not pretend to decide anything in this regard; we only wish to clear up, as far as possible, a very obscure subject, and, in a question of such importance, we shall be very well satisfied if we have made it apparent that the principal objection to the identity of the forces which produce electricity and magnetism is rather a difficulty of reconciling facts than of the facts themselves."

And again, on page 238, he says:—"Steel when heated loses its magnetism, showing that it becomes a better conductor by the elevation of temperature, like electrical bodies. Magnetism, too, like electricity, exists in all bodies in nature, as Bruckmann and Coulomb have shown. From this it seems that the magnetic force is as general as the electric; and it remains to be seen whether electricity in its most latent state [*i.e.*, as galvanism] will not affect the magnetic needle *as such*.

"This experiment will not be made without difficulty, for the electrical actions will blend and render the observations very complicated. In comparing the attractions on magnetic and non-magnetic bodies, some *data* will probably be obtained."

In trying experiments with a view to the illustration of those hazy notions Oersted is said to have succeeded in obtaining indications of the action of the conducting wires of the pile, during the passage of electricity, on the needle; but the phenomena were, at first view, not a little perplexing; and it was not till after repeated investigation that, in the winter of 1819—20, the real nature of the action was satisfactorily made out.*

Even then Oersted seems not to have clearly understood the full significance of his own experiment. Unlike Davy, who, when he first saw the fiery drops of potassium flow under the action of his battery, recorded his triumph in a few glowing words in his laboratory journal,† Oersted took no immediate steps, either to complete, or to publish, his discovery. "Although," he says "the effect was unquestionable it appeared to me, nevertheless, so confused that I deferred a minute examination of it to a period at which I hoped for more leisure." (Tyndall's Lectures on Voltaic Electricity at the Royal Institution, 1876.) And when he had made this minute examination and published the results, he could not explain the phenomena by a better hypothesis than that negative electricity acts only on the northern pole, and positive only on the southern pole of the needle.‡

* The author reserves all rights of translation.

† Chapter VIII., pages 235-6 of the French edition, "Recherches sur 'Identité des Forces Chimiques et Electriques," Paris, 1813.

* "Professor Forchhammer, the pupil and friend of Oersted, states that, in 1818 and 1819, it was well known in Copenhagen that he was engaged in a special study of the connection of magnetism and electricity. Yet we must ascribe it to a happy impulse—the result, no doubt, of much anxious thought—that, at a private lecture to a few advanced students in the winter of 1819—20, he made the observation, that a wire uniting the ends of a voltaic battery in a state of activity affected a magnet in its vicinity."—*Ency: Brit:* 8th Ed. Dissertation VI., p. 973.

† On 16th October, 1807, while investigating the compound nature of the alkalies. On seeing the globules of potassium burst through the crust of the potash, and take fire as they entered the atmosphere, he could not contain his joy, but danced about the room in wild delight, and some time elapsed before he could sufficiently compose himself to continue his experiments. (Bakewell's "Manual of Electricity," London, 1857, page 34.)

‡ See concluding paragraph of his paper in the *Journal of the Soc. of Tel. Engs.* Vol. V., p. 468.

Digitized by Google

This most important discovery may be thus briefly defined:—Supposing the electric current to pass from north to south through a wire, placed horizontally in the magnetic meridian, then a compass needle suspended above it will have its north end turned towards the west; if below the wire, to the east; if on the east side of it the north end will be raised; and if on the west side, depressed. These results Oersted first published in a Latin tract, dated the 21st July, 1820, a copy of which (with translation in English) will be found in the *Journal of the Society of Telegraph Engineers*, Vol. 5, pp. 459—69.

The effect of this pamphlet was most wonderful. The enthusiasm, says Lardner (Vol. 1, p. 205), which had been lighted up by the great discovery of Volta twenty years before, and which time had moderated, was relumined, and the experimental resources of every cabinet and laboratory were brought to bear on the pursuit of the consequences of this new relation between sciences so long suspected of closer ties. The inquiry was taken up, more particularly, by Ampère and Arago, in France; by Davy, Faraday, Cumming, and Sturgeon, in England; and by Seebeck, Schweigger, De la Rive, Henry, and numerous other philosophers in all parts of Europe and America.

Among these Ampère has assumed the first and highest place. No sooner was the fact discovered by Oersted made known than that philosopher commenced the beautiful series of researches which has surrounded his name with so much lustre, and brought electro-dynamics within the pale of mathematical physics. On the 18th of September, 1820, within less than two months of the publication of Oersted's experiments, he communicated his first memoir on electro-magnetism to the Academy of Sciences.

In this paper was explained the law which determined the position of the magnetic needle in relation to the electric current. In order to illustrate this he proposed that a man should imagine the current to be transmitted through his body, the positive pole being applied to his feet and the negative pole to his head, so that the current shall pass upwards from the feet to the head. This being premised, a magnetic needle, freely supported on its centre of gravity, and placed before him, will throw itself at right angles to him; the north pole pointing towards his left, and the south pole towards his right.

If the person through whose body the current thus passes turn round, so as to present his face in different directions, a magnetic needle, still placed before him, will have its direction determined by the same condition; the north pole pointing always to the left, and the south to the right.

In the same memoir were described several instruments intended to be constructed; especially spiral, or helical, wires, through which it was proposed to transmit the electric currents, and which, it was expected, would thereby acquire the properties of magnets, and retain these properties so long as the current might be transmitted through them. The author also explained his theory of magnets, ascribing their attractive and directive powers to currents of electricity circulating constantly round their molecules, in planes at right angles to the line joining their poles; the position of the poles, on the one side or the other of these planes*, depending on the direction of the revolving current.

While Ampère was proceeding with these researches, Arago directed his inquiries to the state of the wire through which the current was transmitted, so as to determine whether every part of its surface was endowed with the same magnetic properties. With this view he placed iron filings around the wire, and found that they adhered to it so long as the current flowed, and fell away immediately the connection with the battery was broken. He also found that on placing small steel needles across the wire through which a current from a voltaic pile, or a discharge from a Leyden jar, was sent they were attracted and, on removal, were found to be permanently magnetised. Acting upon Ampère's theory of magnetism, he placed in a glass tube an ordinary sewing needle, and wound round the tube a copper wire. On sending a current through this wire the needle was magnetised, its polarity depending on the direction of the current. If the helix were right-handed, the north pole was found at the end at which the current entered; and if left-handed, the same end was a south pole.†

In the same way he was able to impart a temporary magnetism to soft iron wires. (*Annales de Chimie et de Physique*, Vol. 15, p. 93.)

Another important discovery, which followed fast on the heels of Oersted's experiments, was that of Schweigger, of Halle, announced on the 16th September, 1820. Observing that the deflection produced by the outward current of a battery flowing over the needle was the same as that of the return current under the needle, he made the wire proceed from and to his battery above and beneath the needle, and obtained, as he expected, twice the effect; by giving the wire another turn round the needle the effect was again doubled; a third turn produced three times the original deviation; a fourth, four times, and so on. This effect may be thus formulated:—If a magnetised needle, free to move, be surrounded by a number of convolutions of insulated wire, the power of the current to deflect it will increase in proportion to the number of convolutions.* In this way the effect of a very feeble current may be so multiplied as to produce as great a deviation of the magnetic needle as would otherwise be produced by a very strong current.

On this principle are constructed instruments for indicating and measuring currents of electricity, called *electro-magnetic multipliers*, or, more commonly, *galvanometers*†—the former being the name originally given to the arrangement by Schweigger. His first contrivance was a very humble affair, consisting of a small compass-box, round which were coiled several turns of copper wire in a direction parallel to the meridian line of the card.‡ Yet this was the prototype of the beautiful instruments of Du Bois-Reymond and Sir William Thomson, in the former of which as many as 30,000 convolutions are sometimes employed.

(TO BE CONTINUED.)

## THE INDIAN AND ORIENTAL ELECTRIC STORAGE AND WORKS COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on Friday the 21st inst., at the Cannon Street Hotel, Mr. Ernest Noel, M.P., in the chair.

The SECRETARY (Mr. H. Cleland Heywood) having read the notice convening the meeting,

The CHAIRMAN said the only effect of the resolution he had to propose was that £50,000 of shares, that was to say, the 10,000 shares that they were bound under agreement to give to the parent company, instead of being ordinary shares, would be deferred shares, and until a cumulative dividend of 5 per cent. had been paid on the other shares no dividend would accrue to them. He thought that every one would see that, supposing the Company was successful, or moderately successful, this would be a great advantage, because, knowing the difficulties that they had, knowing that all electric progress had been impeded, they could not look for very large results immediately, and that being the case, to be relieved from paying a dividend on £50,000 was a very important question. As regarded the rest of the agreement entered into with the parent company, they had made arrangements by which they received from them a new patent of an improved form of accumulator. And here he wished to point out one fact, on which he thought there was a mistake in the minds of some shareholders, and that was, that they supposed they had a right to all improvements in accumulators. It was perfectly true they had a right to improvements on the Sellon-Volckmar, but the accumulator they hoped to obtain was not an improvement on the Sellon-Volckmar. It included the Faure patent, and not the Sellon-Volckmar, and therefore they had no claim whatsoever for this new accumulator. They could not enforce any claim for it whatever. He might also point out this, that unless they had made the arrangements which they did some time ago, by which they obtained the Faure patents, which they had not originally when they went into this—wisely or unwisely had nothing to do with it—but when they went into the matter they purchased the Sellon-Volckmar patents, and the purchase of those patents was all they obtained; but when he found the Faure patents were more or less liable to oppose them, and that the parent company was going to obtain those Faure patents, he made the most strenuous exertions to obtain them for this Company. And they did obtain them, and all they gave for them was that they paid in advance royalties which otherwise they would have to have paid supposing the Company went on. If they had not done so they would not now be able to become possessors of the new accumulator that would, no doubt, obviate a very large number of the defects they had found in the Sellon-Volckmar patents in India. But that would be a subject they would go into more fully at the genera

* *Annales de Chimie et de Physique*, Paris, 1820, Vol. 15, pp. 59 and 170.

† Soon after, and before any knowledge of Arago's experiments had reached England, Davy also succeeded in magnetising needles by the voltaic current, as well as by ordinary frictional electricity, and showed the effect of the conducting wire on iron filings. See his letter to Wollaston, dated November 12, 1820, in the *Phil. Trans.*, for 1821. About the same time Seebeck communicated a paper to the Berlin Academy on the same subject.

* The practical reader is, of course, aware that this definition is not strictly true,—for three reasons: 1st, as the convolutions increase, the strength of the current decreases, by reason of the increased resistance in the circuit; 2nd, each convolution has less and less effect, as it is farther and farther removed from the needle; and, 3rd, the current exerts less and less force on the needle, as it is deflected farther and farther from the plane of the current.

† In the early part of the century this name was applied to measuring instruments based on the chemical and calorific properties of the current; but these are now denominated *voltameters*, and the name *galvanometer* is reserved exclusively for the class of apparatus described in the text.

‡ Schweigger's *Journal für Chemie und Physik*, Vol. 31, pp. 1—17. A galvanometer of different form, called a *Galvano-magnetic condensator*, with vertical coils, and unmagnetised needle, was shortly after, but independently, devised by the celebrated Poggendorff, then a student at Berlin. As the *published* description of his apparatus preceded that of Schweigger's, he is sometimes regarded as the first inventor (Gilbert's *Annalen der Physik*, Vol. 67, pp. 422—29).

Digitized by Google

meeting. This was only a resolution, which put the shareholders of this Company in a very much better position, so far as half of the paid-up capital was concerned. He therefore thought there could hardly be two opinions as to the desirability of passing the resolution, and he moved, "That the directors be, and they are hereby authorised to accept the surrender by the Electrical Power Storage Company (Limited) of the 5,000 fully paid shares, numbered 30,001 to 35,000, both inclusive, now held by them, and to issue in lieu thereof 5,000 deferred shares, such as hereinafter mentioned, and that of the 80,000 shares forming the original nominal capital of the Company 10,000 shares shall be deferred shares and the remaining 70,000 shares shall be ordinary shares, and that the deferred shares shall not be entitled to dividend in any year until a dividend of 5 per cent. for that year and every previous year from the 31st December, 1883—or from the issue of the ordinary shares as to any issued subsequent to that date—shall have been earned upon the ordinary shares; but when such dividend of 5 per cent. shall be earned as aforesaid, the said 10,000 deferred shares shall be entitled to receive out of remaining profits a 5 per cent. dividend, and after provision for same to participate for dividend in the residue of the profits equally with the ordinary shares upon the full amount credited as paid upon the said deferred shares."

Mr. BULLIVANT seconded the motion.

Mr. BEDFORD moved an amendment adjourning the meeting until after the general meeting.

Mr. BANBURY seconded the amendment.

The CHAIRMAN: As it can be legally done I have no objection to that, and we will go on to the general meeting.

The SECRETARY read the notice convening the meeting, and the report of the directors was taken as read.

The CHAIRMAN: I have to move that the report of the directors and statement of accounts to the 30th November, 1883, submitted to this meeting, be received and adopted, and in doing so I would very briefly give an account of what has been done in India. For the first few months after the formation of this Company it was found impossible to obtain from the parent company any cells to send out to India. The Eastern Electric Company at that time was very anxious to have batteries sent out. We got reports from our executive saying that batteries were absolutely essential. I was looking this morning at a letter written soon after the formation of the Company, stating that batteries were absolutely essential, and urging that they should be sent out as soon as possible. We took every step in our power to get those sent out, and a certain number were sent out. It would take too long to go through the various mishaps which took place with regard to those batteries, but I will briefly say this, that all the batteries that were sent out were packed in such a way that when they arrived they were worthless, they could not be used. I do not mean to say that none of them were put together by the electricians of the Eastern Company and found to give them satisfactory results for a short time; but they were found permanently unworkable. The boxes leaked, the plates expanded, and other things rendered them simply unworkable. We then found that it was thought the Eastern Company's electrical engineers were not quite competent to deal with this new invention, and we asked what I may call the parent company to send out somebody from their own works who was fitted to put up these batteries, and direct them so that they could be worked efficiently. I am sorry to say the first man who was sent out found that the plates that were sent out were inefficient. We have not yet had time to go into the question as to the real cause of the inefficiency of the batteries. The engineer of the Eastern Company only returned to England two days ago. I have had some time with him, but I have not had sufficient time to at all unravel the grave differences of opinion that I find exist between him and others who were engaged in the working of these batteries. In a few days another gentleman will arrive from India, who will also be able to give us some information, but the first gentleman who was sent out, Mr Gee, from the parent company, certainly failed to erect useful batteries. He can give his reasons for that failure. Whether they are accurate ones I have not been able to discover yet. We said we must have these, for in the meantime the Eastern Electric Company was being seriously injured in its work. Incandescent lighting was earnestly demanded in Bombay, and without this we were unable to furnish that incandescent lighting. The demand in Bombay is very great and very urgent, and there were large numbers prepared to take this lighting, so a second man was sent out by the parent company, and he put up some more batteries. I am sorry to say that from some cause or other, which we shall have to investigate, those batteries, though they worked for a time, did not work satisfactorily, and the persons employing them—those who took the light in Bombay—were so dissatisfied that they said unless it could be better done they would not continue it, and I believe at this moment there are no batteries at work in Bombay. The lighting was undoubtedly inefficient through that. I would further remark that we have not been able to unravel the causes of this; but the non-working of those is no proof of the value of the batteries themselves. What the batteries are can be seen in this country. If they can work in this country they can work in India. We cannot do anything more in India than we can do at home; but if they can be successful here they can be successful there. The new accumulator which has been obtained for us obviates a very large number of those special difficulties that we found in Bombay. They obviate the use of boxes, which has been found one of the gravest sources of difficulty out there. All our earlier failures seem more or less connected with the want of efficient boxes, but that is now obviated by this new accumulator. What, however, I want to point out to the shareholders chiefly, and what I think they will be more interested in, is what we propose to do in the future. As regards the payment of the £5,000 to the parent company, on that question the directors have simply no choice whatsoever. That £5,000 is due to the parent company; whether it was a good bargain or a bad bargain is nothing to do with the question. It was due to the parent company under an agreement, a stamped agreement, by this Company, and was approved by the shareholders of this Company, and what was more, that £5,000 goes to pay for really what is probably a most valuable asset of this Company, that is to say, the securing to us of all that is in the Faure patents in any conceivable new form, just like the form that has been brought out by M. Philippart. We propose that this Company should carry on no tentative work of its own, for it seems to us that the Company should confine itself to seeing at present what others can do. Knowing this, that if it can be shown in this country that tramways or other work can be done by the new accumulator, then I will venture to say that this Company has got a better field for its work than any other company in the world. Whatever have been the failures that have been made Major Strutt will tell you at least this, that for tramway purposes, or for incandescent lighting, the demand in India is very great, but they are not prepared to take the incandescent lighting that fails, and, of course, nobody is going to take tramway work till it has been shown to be a real success in this country. I believe myself, as far as I can judge, that the new accumulator and the new motor have apparently—I can make no promises—solved this question. A tramway has been run in Paris with a set of searching experiments in which they overcame all the difficulties that beset the introduction of electrical tramcars in this country. If the shareholders are willing, of course it is for them to judge, to adopt the view of the directors, it is just simply this:—We have no choice as to the paying the £5,000. It must have been paid before, but the patents for Ceylon were not completed. If the shareholders take our view, it is simply this—that we reduce our expenses to a minimum; that the directors take either no fees, or moderate fees—our other expenses will be reduced to a very small amount—and we will just wait till we see the result of the experiments of others in new batteries and new motors. When we can see an electric tramway running in this country successfully, then I venture to say that there is a great opening and a large profit for this Company. At the same time the directors are quite willing to resign, but while I am on the Board I am quite ready to undertake that we will enter upon no expenditure of any considerable amount whatsoever involving a fresh call without first calling the shareholders together, and informing them of the nature of the enterprise we propose to them, and getting their views. The amount, therefore, that they can further lose is very, very small. They have bought some patents. They have a very, very valuable field if those patents are valuable. I have only one point further to point out, and that is that the course we are now proposing is the one which, after careful consideration, I am perfectly convinced is the best, and being a considerable shareholder myself, I would not have proposed it unless I felt perfectly sure it was in the interest not of directors or patentees, but of those who hold capital in this Company.

Mr. BULLIVANT: I beg to second the resolution, and I think that there can be very little doubt the action we propose to take now is the proper action. It was quite impossible for us as directors to prevent the payment of this £5,000. We should have put the Company in a very awkward position if we had objected to do so. If we had not paid it we should have been liable to an action, and if this Company was called upon to wind up we were in this position—we should have been bound to have called up the whole of our capital, and what we have done at the present time is to call up just sufficient to pay off that liability of £5,000 and leave a small sum in hand to see how the new patents we have acquired work. We shall not call up any money to experiment with, but leave the parent company to carry out the experiments, which, if successful, we shall have an opportunity of taking advantage of.

Mr. BRAITHWAITE said that the statement they had heard that day, compared with the statements of the prospectus on which they subscribed their money, appeared to show a great change of front. He was sorry that they did not see all the directors present, and as they had taken over £2,000 in fees it would have been an act of common civility to have appeared before the shareholders. There were two points which specially recommended this Company—its apparent security, and no promotion money was to be paid. It was said the business was a safe one, there was no risk, they had merely to buy the batteries from the parent company, and sell them to the Eastern Electric Lighting Company, and, therefore, they could not make a loss. They might do no business, but if they did they would make a profit. It was also stated that the Eastern Electric Company were prepared to give them an order for 3,000 horse-power at once, and if that had been carried out it ought to show some profit. It was also stated that the Eastern Company guaranteed preliminary expenses, but in the balance-sheet he saw £3,256 1s. 5d. put down for those, and he should like to know why the Eastern Company had not paid that amount. It appeared now that the directors wanted them to buy another battery.

The CHAIRMAN: No, we do not buy another battery. It is freely given. We do not pay one sixpence for it.

Mr. BRAITHWAITE: I understood there was another £5,000 to be paid.

The CHAIRMAN: It is £5,000 due under agreement, which the parent company could go into court to-morrow and get a judgment against us for. We have no kind of defence. It is as much a sum owing as on a bill, or more. Mr. Braithwaite evidently was not here at the last meeting, because what he is now speaking about was passed by the shareholders after the fullest explanation of what was done, and they approved it.

Mr. BRAITHWAITE said that they purchased the Sellon-Faure-Volckmar patents, and therefore, if they had to acquire a fresh accumulator, it must be something quite outside those patents. If the directors had stuck to the original prospectus and to the business as laid down in it, they would not have made a loss, but he observed that the directors had speculated in turbines and engines, which were quite outside the operations of the Company. Now the chairman suggested that other people should make experiments, and that they should supply the articles when the demand arose. He thought that if that policy had been carried out from the first they would have been in a very different position to-day.

The CHAIRMAN replied that most of Mr. Braithwaite's statements were really answered at a previous meeting in a speech that he made. That meeting was very largely attended, and there was not a single shareholder who had not had notice of it. The statements that he then made were as clear and as plain as anything could possibly be as to what was the nature of that engagement, and at that time he certainly thought, and he now thought, that they did not make a bad bargain. They might have made a very bad bargain in buying the Sellon-Volckmar patents, but no director was any more responsible for that than any shareholder. With regard to the £25,000, that was all fully explained in July, and was passed and approved by the shareholders. They were not now asked to buy anything new; if they were, he certainly should not be there to propose it. Not one sixpence had they to pay for anything that was offered. If they chose to say they would not receive the gift of that patent well and good, but he could hardly conceive any shareholders refusing to receive a free gift of what might ultimately prove to be a valuable property. If they chose to wind up he had no hesitation in saying that they would be called upon to pay a pound a share simply to go into the coffers of the Electrical Storage Company

REESE LIBRARY OF THE UNIVERSITY OF CALIFORNIA.
Digitized by Google

Mr. BANBURY asked whether it was impossible to arrange better terms with the parent company. He thought the directors should devote their energies to see if they could get some concession from them if they gave back the patents. In the original prospectus they were given to understand the parent company protected them against any infringement, but afterwards this Company was required to pay £25,000

The CHAIRMAN said that the whole thing had been explained at a previous meeting, and was carried by a direct vote of the Company. It took him half an hour or more to show what was their position as regarded the guarantee, and what dangers they would have had if they had rested solely on that guarantee. He believed they did wisely in securing the Faure patents, but at all events that was something this Company had no power over. With regard to whether they could do more in negotiation, he had been doing what he could, and he confessed that he found that he could not negotiate better terms than he had obtained. He had secured, as he thought, two very considerable concessions—first, that £50,000 was made deferred capital, which received no dividend till a cumulative dividend was paid on their shares of 5 per cent., and then they had secured the new patent of M. Philippart, which he believed was a very great improvement on the Sellon-Volckmar. It was not exactly an improvement, because it was quite a new invention outside the Sellon-Volckmar. That had cost the other Company a considerable amount of money, but in this Company they had it given to them for nothing. If there were any shareholders who wished to join the Board, they were only too welcome to do so, and for his own part he should be most happy to resign.

Mr. BEDFORD said that £25,000 had been paid within thirty or forty days of the closing of the list of the applications for shares, and he thought the shareholders should have some information as to why this was done. He questioned whether it was legal.

The CHAIRMAN said that that was to obtain the Faure patents throughout the East.

The SOLICITOR said that he was a shareholder as well as solicitor of the Company, and there was one matter to which the chairman had not directed their attention. It had been asked whether further negotiations could be made with the parent company. The parent company had said that they had gone as far as they would go, and they tied this Company up to pass the resolution within a limited period, and the matter would go off if it were postponed. If this were done they would have to go into liquidation, when the capital would have to be called up in order to put themselves in a similar position to the other Company in regard to the distribution of the assets.

Mr. BEDFORD said that he would rather pay a pound a share and have done with the Company.

The CHAIRMAN said that he would take the shares of any shareholder on those terms, and therefore any shareholder who chose could at once terminate his connection with the Company in that manner.

Major STRUTT said that he did not agree with the legal opinion which the Company had had, that, in the event of winding up, it would be necessary to call up the uncalled capital of the Company, and he thought that a further opinion of counsel should be obtained in regard to this matter. With respect to the £25,000 which had been paid for royalties, that had been done when he was absent, and if he had been present he certainly should not have agreed to it.

Mr. BEDFORD asked if they had no remedy against the Storage Company for furnishing accumulators which were useless.

The CHAIRMAN replied that the only reclamation they had was not to pay for those that were not in good order.

Mr. BEDFORD said it appeared to him that a question of damages arose.

The CHAIRMAN said that it would not be damages to this Company, but to the Electrical Storage Company.

Lord GEORGE CAMPBELL thought that further negotiations should be opened with the parent company in order to obtain a modification of the terms of the original agreement.

After some further general conversation, it was resolved that the meeting should be adjourned until the 2nd January, and that a committee consisting of Mr. Banbury, Mr. Braithwaite, Mr. Cumberbach, Mr. Bedford, and Lord Walter Campbell should be appointed to confer together with the directors of the Eastern Electric Company with the view of obtaining a modification of the terms of the original agreement, especially in regard to the payment of the £5,000.

The meeting then adjourned

## THE INTERNATIONAL ELECTRIC COMPANY (LIMITED).

Report of the directors to be submitted to the second ordinary general meeting of shareholders, to be held at the Company's offices, 4, Copthall-buildings, London, E.C., on Monday, the 31st inst., at 1:30 p.m.:—The directors have pleasure in informing the shareholders that the company's business is emerging from the preparatory and entering upon the productive stage. Contracts have been entered into for the carrying out of electric light installations to the gross value of 165,612 florins (£13,801) payable in cash. The Company has also entered into lighting contracts, under which the gross revenue is 91,696 florins (£7,641) per annum, with an early prospect of increase to 134,512fl. (£11,209) per annum. The Company has contracted for lighting the whole of the Imperial Opera House in Vienna (this contract was signed and sealed by the Opera Administration on the 2nd of December, and merely awaits Imperial ratification); for lighting the town of Temesvar in Hungary, and for the supply of the conductors and internal fittings for an installation of 1,400 lamps in the palace of the King of Roumania at Bucharest. Careful calculations, based on the results of practical experience, show that the contracts entered into may be fairly relied upon to yield considerable profits. It is worthy of mention that the Vienna Imperial Opera House contract was only signed after an exhaustive trial, lasting over six weeks, had been made of the Company's system of lighting the stage; after full investigation had been made by a commission appointed for the purpose of all that was to be seen at the Vienna Electrical Exhibition, and after the proposals of the Company had been referred to and reported upon by the highest technical authority in Austria. The possession of the Vienna Imperial Opera House contract under these circumstances may be regarded as evidence that the Company has earned the confidence of official circles. As regards prospects in connection with installations of this character, it may be mentioned that it is the expressed intention of the Austrian Government to light by electricity the whole range of magnificent Government buildings which line the "Ring" in Vienna, and which are now nearly completed. It is also the intention to adopt electric light in the new and old Burg Theatres, in the new municipal buildings, as well as in the old and new Imperial Palaces in Vienna. These contracts, some or possibly all of which the directors trust they may obtain, will probably be of the same character as the Opera House contract, that is to say a contract for the supply of internal conductors and fittings against payment in cash, and a contract for the supply of light at fixed rates for a term of years by means of generating apparatus to be put up by the contractors at their own cost. As regards the Temesvar lighting contract, the directors believe it will be the forerunner of a very large business in connection with the public street lighting of towns. The street lamps, which are to be 16 candle-power incandescence Lane-Fox lamps, are to be grouped in multiple series, and they will be worked by means of Brush dynamo machines of high electromotive force and small current. It has been arranged with the municipal authorities to keep the public lighting of the streets distinct and separate from private lighting, and permission has been granted to carry the conductors overhead. Under these circumstances the cost of the installation will be comparatively small, whilst the plant will be utilised to its full working capacity during regular and long working hours daily. The difficult problem of economical distribution over a large area is thus solved by the use of a high tension current and light and cheap conductors. The Company is in treaty for the concessions for the public street lighting of five other towns. The contracts entered into by the Company are not sufficiently advanced to enable a profit and loss account to be made out, and the directors can therefore only submit a balance-sheet made up to 31st October last, showing how the funds at the disposal of the Board have been applied. The development of the Company's business has been considerably retarded by the decision generally come to, to await the results of the International Electric Exhibition, which took place last autumn, in Vienna, before entering into any engagements relating to electrical business. Until the exhibition closed in November last it was impossible to bring the more important negotiations to a point, and this delay has necessarily been a source of considerable expense. It is also on this account that the Board deemed it advisable to defer the issue of this report and the summoning of the general meeting. The directors have to report with deep regret the loss of one of their most able and active colleagues, Colonel R. W. Hamilton, who died on the 3rd October last. They also have to report the retirement from the Board of Sir Alfred Slade, Bart. Sir William Stephenson and Mr. C. F. de Kierzkowski-Steuart, retire from the Board by rotation in accordance with the Company's Articles of Association, and being eligible offer themselves for re-election. The Board recommend the election of Lieut.-Colonel A. C. Hamilton, R.E., of Croxted House, Farnborough, as a director to fill up one of the vacant seats. The directors do not think it necessary to fill up the other vacancy at present. The auditors, Messrs. Cooper Brothers and Co., retire, and offer themselves for re-election.

## NOTES.

THE TELEPHONE ON 'CHANGE.—The Bourses of Magdebourg and Berlin are in telephonic communication.

OURSELVES.—We would call the attention of our readers to a notice appearing immediately above this week's leader.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 28th December amounted to £2,627.

LIGHTING WESTMINSTER ABBEY.—A contemporary says that preparations are being made at Westminster Abbey for lighting the edifice by electricity.

A REMARKABLE WEEK.—From the observations taken at the Royal Observatory, Greenwich, for the week ending last Saturday (Dec. 29), the "registered sunshine" is stated to have been "*nil.*"

NEW CABLE AT WORK.—The new cable just laid between Cadiz and the Canary Islands has been opened for traffic. The rate from Great Britain to Teneriffe, Palma, and Gran Canaria is 1s. 5d. per word.

SOCIETY OF TELEGRAPH ENGINEERS AND ELECTRICIANS.—The first meeting of this year will take place on the 10th inst., when the president, Professor W. G. Adams, F.R.S., will deliver his inaugural address.

A STEAM MAGNET.—C. Thouvenot, as did previously Tommasi, obtains an electro-magnet by passing steam of the pressure of two atmospheres through a copper tube of 1·5 millimetre in diameter coiled round an iron core.—*Wiedemann's Beiblätter.*

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending Dec. 28 were £2,463, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company (Limited).

ELECTRIC LIGHT IN BEDALL HALL.—Last week Mr. Hartnell, of Leeds, lighted up a large room in Bedall Hall, near Northallerton, Yorkshire, for Sir Henry Beresford Peirse, with fifty-six Swan incandescent lamps. The installation was very successful.

ELECTRIC LIGHTING ON SHIPS.—The new despatch boat "Dolphin," now being built for the American navy, will be lighted by electric lamps, and will have electric search and head lights. Her length will be 240ft., speed 15 knots, and indicated horse-power 2,300.

A MICRO-THERMOMETER.—Under this title M. F. Larroque described, at a recent meeting of the French Academy of Sciences, a very delicate thermometer he has constructed for measuring small variations of temperature. It will, the author says, measure a variation of one-thousandth of a degree.

THE NEW PATENTS ACT.—On Tuesday last this Act came into operation. Mr. H. Reader Lack, who was clerk to the Commissioners of Patents, and Registrar of Designs and Trade Marks, has been appointed Comptroller-General of Patents, Designs, and Trade Marks, under the new Act.

SUBMARINE MINES FOR THE AMERICAN COAST.—The chief of the United States engineers is calling the attention of Congress to the vast extent of coast line still unprotected, and urging that the work of erecting electrical rooms and cable galleries where they are most wanted be undertaken at once.

THE TRANSMISSION OF ENERGY.—The Italian Government have decided to award a premium of 10,000fr. (£400) to any one who shall perfect the most practical and usefu system for generating and transmitting electrical energy. This premium is offered in connection with the Turin Exhibition.

PRIVATE TELEPHONE LINES.—Telephonic communication has been established between Worksop and Clumber (the Nottinghamshire seat of the Duke of Newcastle), and between various places on the estate, by Messrs. Tasker, Sons, and Co., of Sheffield. Johnson's transmitters and Bell's receivers are used.

THE LATE SIR WILLIAM SIEMENS.—The Prince of Wales, as President of the Society of Arts, has transmitted to Lady Siemens the resolution passed after the death of Sir William Siemens by the council of that association, and in doing so has expressed his own appreciation of Sir William Siemens's labours.

EARTHQUAKE. — A Reuter's telegram, dated Prague, December 27, says:—"Zepec, Bohemia, was last night visited by a severe shock of earthquake, which lasted three seconds. The inhabitants fled into the neighbouring fields where they remained during the night. The damage caused by the shock was, however, unimportant."

CABLE FOR TONQUIN.—A Reuter's telegram, dated Paris, December 29, says:—"The Minister of Posts and Telegraphs has ordered 3,800 metres of submarine telegraph cable to be forwarded to Toulon, of which 2,000 metres are intended for Cochin China, and 1,800 for Tonquin. The cables will be despatched from Toulon by the first transport leaving next month."

THE TELEPHONE AT DOVER.—Telephonic communication is being laid between the turret on the Admiralty Pier, Dover, and the Western Heights and Castle and other military positions on shore. The object of this is that in case of actual warfare the working of the guns may be directed from a more elevated position; also that easy communication may be secured.

NEW BOOK.—Mr. Musgrave Heaphy, who is well known in electric lighting circles as an able representative of the Phœnix Insurance Company, has just published a little book entitled "Glimpses and Gleams." It has been written in the leisure moments of a busy life, and treats of sanitary scientific, and moral questions in a light and readable style. It is published by Chapman and Hall, of Henrietta-street W.C.

THE PHILADELPHIA ELECTRICAL EXHIBITION.—In addition to the exhibition of electrical appliances and processes which it is proposed to hold in Philadelphia next September under the auspices of the Franklin Institute, the idea of convening an electricians' conference has also been put forward. The United States Congress is, we learn, expected to authorise the President to appoint a commission for making the necessary arrangements.

ELECTRO VEGETATION.—This is the heading of a note in the *Family Herald* for April 18, 1863, which runs as follows:—"A salad consisting of mustard and cress may be produced by means of the following process:—Immerse the seed for two or three days in diluted oxymuriatic acid, after which sow it in a very light soil, and place over it a metallic cover; then bring it in contact with an electric machine, and the plants will be produced in a few minutes."

PATENT APPLICATION FORMS.—"Inventor" writes to a daily paper as follows:—"Upon inquiring at two important

Digitized by Google

West End post offices—one of them the Pimlico District Office—for a Patent Application Form, I was met by the counter inquiry, 'What did I mean?' the Postmasters having heard nothing about them. I make no comment upon the significance of this fact, but should like to know whether the same delay is being experienced in other localities."

Telephone Poles.—In a certain city in the United States a local telephone company asked permission of the proprietor of the local opera house to place a telephone pole in front of it. The proprietor refused. The telephone company, not to be baulked, sent a gang of men one night, and when the proprietor of the opera house drove up the next morning, there it was. On the following morning, however, the telephone company's *employés* found the pole lying in the street gutter.

Electric Lighting at Bowdon.—Culcheth Hall, Bowdon, Cheshire, the residence of Mr. Ellis Lever, has recently been lighted by incandescent arc lamps. The entrance gates and hall door were lighted by Lever arc lamps, the invention of Mr. Charles Lever, son of Mr. Ellis Lever, and inside the hall Swan lamps were used. The current was supplied by a Gramme and Bürgin dynamo, driven by a Marshall engine. The incandescent lights were much appreciated on the occasion of a dance given by Mr. Lever.

A Heavy Contract.—The contract for the construction of the line of the Bankers' and Merchants' Telegraph Company between Pittsburgh, Columbus, Cincinnati, and St. Louis, has been awarded to John H. Miller, of Pittsburgh, and J. H. Borland, of Wilkesbarre. Mr. Miller is an old telegrapher, and was largely engaged in the construction of the American Rapid lines. The terms of the contract are private. It includes the construction of the lines between all the points named, but does not require the building of the lines through the cities where underground cables will be used.—*Electrical World.*

The Telephone in Brussels.—The central telegraph office in Brussels is now in telephonic communication with the Telephone Exchange, and subscribers to the latter can be connected up to the former, and verbally dictate telegrams to the telegraph clerks for despatch to their destinations. On the other hand, subscribers can have any telegrams that may be received at the telegraph office for them repeated verbally to them per telephone. A copy of the message is subsequently sent per post and free of cost, so that the recipient may be sure it was correctly telephoned to him. Should a subscriber be called up and not answer within five minutes the message is despatched to him per messenger as usual.

Catalogue.—We have received a copy of the catalogue issued by Messrs. Francis and Co., of the Eagle Telegraph Works, Lawford-road, N.W. It contains diagrams showing how to fit up electric bells, with particulars as to prices, &c. We also find the price of wire, insulated and uninsulated, batteries and battery plates, gutta percha sheets, tubing, &c. A useful table giving the diameter, weight, and breaking strain of iron wire of different gauges is given on p. 29. Messrs. Francis no doubt know what suits them best, but we venture to think that the size of their catalogue might be modified with advantage. An 8vo. or small 4to. catalogue has far more chance of being kept than the large size they have fixed upon.

Distant Thunder.—There is some disquieting talk going on in the City concerning the position of one or two of the electric light companies. Shareholders are proverbially impatient, and it is no secret that some at least of those who were induced to invest in the electric light companies have bitterly repented their temerity, and if one-tenth part of the mutterings which we hear find utterance at the forthcoming meetings some of the directors will have a lively time of it. The slow progress that is being made in carrying out the provisional orders granted by Parliament is one great source of dissatisfaction, and unless very good reason is shown why so little has been done the prevailing dissatisfaction may find voice in very practical shape.—*Pall Mall Gazette.*

Electric Lighting in Foundries.—Messrs. Pollit and Wiggett, engineers, of Sowerby Bridge, have recently adopted the electric light in their works. They have had the Crompton-Bürgin machine and five DD lamps put up, three of which are placed in the foundry, and the other two in the erecting and heavy tool shop respectively. The two last-named were only intended to give a general light in each shop, but this light is so powerful, and burns so steadily, that but very few gas lights have to be used. Hitherto it has not been deemed advisable to burn less than two arc lamps on account of the shadows, but Mr. Hartnell, of Leeds, who carried out the work, has given practical proof that for general purposes one lamp only is needed.

The Burning of the Brussels House of Parliament.—A Belgian contemporary points out that the burning of this national building was brought about by the use of sun-burners, as they are called, or an aggregation of gas jets beneath a reflector. It reminds us that electric lighting on two systems, the Lampe-Soleil and the Edison, were tried some time since in portions of the house, notably the library, and given up as being too dear. Our contemporary asks what is the difference between the extra amount to be paid for electric lights and security, and gas which leads to the loss of an invaluable library and costly building, the rebuilding of the latter of which will take many a pound out of the pockets of the nation, whilst the former cannot be replaced?

The Colon-Jamaica Cable.—With reference to the notification of the interruption of this cable published in last week's notes, the West India and Panama Telegraph Company state that the date of the interruption was the 19th December, and that the company's steamer "Grappler" will proceed to its repair. That steamer has recently repaired portions of the original Porto Rico Jamaica cable, but has encountered some difficulty in her operations, and it is expected that more new cable will have to be used than was at first anticipated. The St. Vincent-Grenada cable was interrupted on the 22nd inst., and the company's second repairing steamer, "Duchess of Marlborough," has proceeded to effect its repair. All stations except Colon are, however, in telegraphic communication.

Electric Lamps for Mines.—Mr. Walton Smith writes to a daily paper urging the adoption of incandescent lamps for the lighting of mines, as a preventive against many of the explosions that take place. He concludes with an appeal to colliery owners as follows:—"Let your new year, 1884, begin with the resolution to endeavour to form an association having the object unitedly to introduce the closed electric lamp as well as telephone arrangements. Do not wait for compulsion by Act of Parliament, for there is no virtue in doing right because compelled to do it. If electric lamps be used and properly arranged in the mines, if telephones be adjusted, and, finally, if blasting be confined exclusively to the explosion of lime cartridges, then the bare possibility of gas explosions in coal mines will be all there is left to dread, and that only in cases of criminal foolhardiness."

A Photo-electric Battery.—Herr Sauer has constructed a battery which is dependent upon luminous radiations for its action. It consists of a glass jar, holding a solution of

Digitized by Google

15 parts of common salt, and seven parts of sulphate of copper in 100 parts of water. In this jar is placed a porous cell, containing mercury. One of the electrodes is a platinum plate; the other consists of sulphuret of silver. When not in use the battery is enclosed in a box. When in use the platinum electrode is immersed in the mercury, and the other electrode in the saline solution. The sulphuret of silver becomes the negative pole. The deflection given by a galvanometer connected to the two poles depends upon the intensity of the source of light. If the sky be cloudy, or any change in the light takes place, it is at once indicated by the galvanometer needle.

Electric Lighting in Halifax.—We understand that electric lighting is being extensively introduced into Halifax. Twenty-six Hochhausen arc lamps are distributed among eleven shops in the principal parts of the town. The lamps are each of 2,000 nominal candle-power, and are run from a Hochhausen dynamo machine stationed at Messrs. Edmunds and Co.'s works, the whole circuit being over a mile in length. Besides this, a portion of the works of Messrs. J. and J. Baldwin, of Clark Bridge Mills, in that town, has for some time past been most successfully lighted with five Hochhausen arc lamps and ninety-six incandescent lamps. We may add that both these installations have been carried out by Mr. Henry Edmunds, of 2, Victoria-mansions, Westminster, London, S.W., who exhibited the Hochhausen system at the Fisheries Exhibition, South Kensington.

The Laying of the Spanish Cables.—We have received a letter from a correspondent with the expedition charged with laying the cables for the Spanish National Company, from which we quote the following:—"At all the islands the ships have been received with the greatest enthusiasm and hospitality. The "Dacia" and "International," having laid the Cadiz-Teneriffe section are now (December 15th) laying the Lanzarole-Gran Canaria and Gran Canaria-Teneriffe section. The "Dacia" leaves for home in a day or so to ship the Senegal cable. We did a tremendous lot of sounding; the "Dacia" was three weeks sounding between Cadiz and the islands, and then sounded between all the islands as well; we took about 400 soundings in all. We had some trouble over this section, and had to do some grappling. In landing the hut here a big cutter was capsized and caged a man underneath it, who was with great difficulty saved from being drowned."

Electric Lighting at Perth.—A few days since a grand *conversazione* took place under the auspices of the Perthshire Society of Natural Science, on the occasion of the opening of the society's museum to the public, Professor Geikie, of Edinburgh University, presiding. The museum was lighted by means of Swan incandescent lamps, as was also the lobby leading to it. One of Siemens's arc lamps was placed at the corner of Canal and Tay-streets. The whole installation was supplied by the Dundee Electric Light Company. In one of the halls was a table on which was displayed a number of different kinds of arc and incandescent lamps, one of the incandescent lamps being of one candle-power, and illuminated by means of an ordinary bichromate battery. In addition to this there were electric motors, pumps, &c. These were under the superintendence of Mr. O. Loring, manager of the above company, who also had charge of the electric lighting installation. The whole was carried out without the slightest hitch.

Meteorological Observatories in Switzerland.—The correspondent of the *Daily News* telegraphed from Geneva on Tuesday last, as follows:—"The Committee of the Central Meteorological Society, Switzerland, has resolved to establish immediately throughout the country a great number of observatories, which will be known as pluviometric stations. Great attention is to be given to all kinds of atmospheric disturbances, and the law of storms is to be carefully studied. The phenomenon of hail will be made a special branch of observation, which will seek to determine how hailstones are formed. Falling stars and meteors are also to be the subject of specific investigation." We have from time to time published the results of the investigations of M. Colladon, a Swiss scientist, into the character of hail, and his theories as to its formation. Switzerland is peculiarly well situated for the study of atmospheric phenomena, and no doubt some very interesting reports will be published by the committee above mentioned.

The United States Telegraphs.—With reference to the agitation for the purchase of railways and telegraphs by the Federal Government, the *Saturday Review* of 22nd ult. says:—"The American public would never consent to place so much patronage in the hands of politicians, or to entrust the Government with expenditure of such immense revenues as would accrue from the purchase of the whole railway system of the country. The purchase of the telegraphs would be a much easier matter. But, in the first place, there is the strong feeling, that to which we have referred above, against all extensions of Federal power. Just now, while the public are smarting under the mismanagement of both railways and telegraphs, they cry out for some remedy, but they would hardly be prepared to see the Federal Government adding the telegraphs to the Post Office. At present the telegraph service is performed by an existing company. In addition it is to be borne in mind that, if the Government were now to buy up the telegraph companies, it would have to deal with capitals which have been swollen enormously by fictitious creations of stock. The speculators who carried through the late amalgamation, and then watered the stock, would thus succeed in making the American public pay them not for actual outlay, but for an entirely fictitious increase of capital."

A Chapter of Accidents.—The Central Union Telephone Exchange, of Dayton, O., says an American contemporary, has again been tried by fire, the third time within the last two years. Last March a large dry goods store occupying the same building, but separated from the exchange by a fire wall, was burned down, and the exchange was slightly damaged by fire and greatly injured by water, no fewer than 150 lines suffering. Last May, during a heavy thunderstorm, the tower of the exchange caught fire by the sparking of the lightning from the arrester to the ground strip igniting the insulation of the cables. The roof of the tower was burned through, and the destruction of about one-half of each of the eleven cables necessitated nearly 550 splices. The third fire occurred on the night of the 7th inst., when the tower was partially destroyed. Owing to defects, it is said, in the line construction of the Electric Light Company, about a dozen telephones have been burned out and as many annunciators destroyed; and on the night named the electric light lines —which do not, as a rule, clear the telephone lines by many inches—became so weighted with rain that they crossed the telephone wires, burned out three instruments and three annunciators, and the tower. It is to be hoped that the exchange has now experienced the last of these trials by fire.

The Electric Light for Contractors' Work.—The firm of Messrs. Walter Scott and Co., the contractors for the new dock at Silloth, Cumberland, has recently adopted the electric light as a means of enabling the work to be carried on at night as well as during the day. After consultation

Digitized by Google

with Messrs. J. H. Holmes and Co., electric light engineers, of Newcastle-on-Tyne, it was decided to make use of a few powerful arc lights in preference to a large number of smaller ones, and the result fully justifies the course that has been adopted. The dock is now brilliantly lighted by means of two arc lights of 6,000 candle-power, each suspended in square lanterns with reflectors on poles at a considerable elevation above the bottom of the dock. Each lamp is supplied with current from a separate dynamo of Siemens make, both machines being driven from the fly-wheels of a portable engine, which is used during the daytime for working a circular saw. The economy in working expenses and the entire freedom from danger point to this system being preferable to any other for work of this kind, and the illumination obtained enables the work of excavating and the laying of masonry to be carried on with the same facility as during the daytime. This installation has been carried out by Messrs. J. H. Holmes and Co., electric light engineers, 67, Westgate-road, Newcastle-on-Tyne.

International Society of Electricians. — At the meeting of the above society, on the 21st of last month, the the following officers were elected:—Honorary president, M. A. Cochery, Minister of Posts and Telegraphs; honorary president of the French Section, M. J. B. Dumas; president, M. Georges Berger. Section 1: Electrical Theory, Electrometers, Lightning Conductors; president, M. Marié-Davy; secretary, M. G. Lippmann. Section 2: Electric Machines and Motors, the Transmission and Distribution of Electrical Energy; president, M. Tresca; secretary, M. E. Hospitalier. Section 3: Electric Lighting, the Heating Effects of Electric Currents; president, M. Jamin; secretary, M. Max de Nansouty. Section 4: Telegraphy and Telephony; president, M. E. Blavier; secretary, M. A. Sabourain. Section 5: Railway Signals, Clocks, and Registering Instruments; president, M. Maurice Lœvy; secretary, M. D. Napoli. Section 6: Electro-chemistry and Electro-therapeutics; president, M. le Comte du Moncel; secretary, M. G. Sciama. The publications committee will have M. le Comte du Moncel for president, and the following gentlemen as secretaries: MM. Armengaud, jeune, Dr. Boudot, G. Cabanellas, G. Masson, G. Tissandier, J. Raynaud, and l'Abbé Valette. Ordinary monthly meetings of the society will be held on the second Wednesday in each month at 8:30 p.m. The next is fixed for January 9.

The Aurora Borealis.—According to a *Daily News* correspondent, who writes from Reykjavik in Iceland, there has been an unusual influx of scientific men into that island during the year past. Amongst others he mentions Professor Sophus Tromholt, well known in scientific circles by his researches respecting the aurora borealis, who, he says, is pursuing these investigations there, and intends to remain all the winter, as from the clearness of the atmosphere and the frequency and brilliancy of the aurora borealis Iceland is excellently suited for his observations. He further says that "reports of a volcanic eruption in the interior of the island were current this year, and seem to have been founded on peculiar circumstances of the sky, and especially on the observation from some of the remote inland farms of columns of smoke or vapour rising in the far distance. Nothing definite has been learned as to these phenomena, but the fact that a large part of the interior of the island is occupied by snow-covered mountains and glaciers, sandy wastes and lava fields, which the natives never penetrate, and which are quite unexplored save by a few enterprising English travellers, such as Mr. W. L. Watts, who crossed the Vatna Jökull, and Mr. W. G. Lock, who explored the crater of Askja, renders it not unlikely that volcanic disturbances may have occurred in the centre of the island without attracting much attention."

Telegraphic Charges to Australia.—With reference to the action of the Postmaster-General of New South Wales, towards a reduction in the charges for telegraphic communication between Europe and the Australian colonies, a letter in reply to that sent from Sydney has been received from the Hon. Graham Berry, Postmaster-General of Victoria. Mr. Berry states that he is entirely in accord with the opinion of the Postmaster-General of New South Wales regarding the charges for cablegrams as referred to by Mr. Trickett, and that the Government of Victoria is prepared to concur in any suitable action which may be taken to obtain a reduction. With respect to the colonies which should co-operate in this matter, the Postmaster-General of Victoria suggests for Mr. Trickett's consideration that the proposal should not be confined to such colonies as are responsible for payment of the annual subsidy for the construction and maintenance of the duplicate cable between Port Darwin and Penang, but that all the Australian colonies should be invited to join in the movement. Regarding the amount of loss, if any, to be made good in the event of the desired reduction being conceded, it would necessarily be, Mr. Berry says, the difference between the present receipts and any less sum received after the change of tariff upon messages passing to and from the colonies. Mr. Berry feels satisfied that the Victorian Government would be a party to a joint guarantee from all the Australasian colonies to make up the amount, if any, of such deficiency.—*Colonies and India.*

Examination Blunderers.—Under this heading the *Standard* of the 3rd inst. has a very amusing collection of somewhat mixed answers to examination papers. We select one or two which will no doubt be appreciated by our readers:—"Elementary science, which is now very fashionable as a school subject, produces hopeless confusion among the blunderers. Tutors perform experiments without sufficiently explaining what each experiment is intended to prove, and the blunderer begins to find the universe a very dark and puzzling place of residence. The Kensington student who thus explained the theory of volcanoes, 'Volcanoes are caused by combustion, for if you dip a glass rod into a plate of lump sugar it flames to the ceiling, and a piece of sodium in water runs about and burns till it bursts,' was evidently suffering from the effects of unexplained experiments. When physiology is taught by means of cheap diagrams, the results on the blunderer's intelligence are fatal. A young person wrote the following statement concerning the process of digestion, 'The food passes through the liver and evaporates by means of little holes called capillaries.' A scholarship competitor lately expressed some very original views on the subject of the 'Channel Tunnel.' He observed that 'No one need be frightened if the tunnel is cut, for it will open with valves that scientific men have made, and the Atlantic would be run in if the enemy came across. Then if we did not kill them with electricity their ships would land, and Mr. Bright would soon defeat them.' We learn that by a remarkable coincidence another candidate cherished a confident hope that 'If the French came into England Mr. Bright would knock them into match-boxes.'"

The Electric Light an Aid to Fishing.—Mr. G. W. Baird, of the United States steamer "Albatross," recently employed to collect specimens of fish for the U.S. Government, gives the following account of the use made of the electric light. After alluding to the readiness with which

Digitized by Google

fish could be induced to enter nets having a small electric light in them, he describes the method adopted by the Edison Company to produce a light for use in deep water. We quote from *Science*:—"The Edison Company first prepared a lantern of two thicknesses of glass, hemispherical in form, with its flat side tightly joined to a bronze disc, on which were placed three 16 candle-power B lamps in multiple arc. At a moderate depth it burned beautifully; but at about a hundred and fifty feet the packing leaked, and, the sea water entering, short-circuited, and the lamp was extinguished by the destruction of the cut-out plug. A similar lamp was then tried with improved packing; but its glass walls were crushed by the pressure of the water, and it was extinguished. The next essay was with a single Edison lamp, its glass vessel being cylindrical in form, with hemispherical end, to give it strength; its thin platinum wires extending through one end without any external attachment. To these delicate wires I succeeded in soldering the copper wires of the cable, but broke (or cut) off one of the platinum wires at the point where it enters the glass, while putting on the insulation. When it is remembered that a hundred fathoms depth of water brings a pressure of over two hundred and fifty pounds per square inch on the lamp, it will be understood that great care was required in every procedure. Our next attempt was with a single Edison lamp exactly the same as the last. I succeeded in soldering and insulating the joints perfectly; but the pressure of the water upon the insulation cut the delicate platinum wire on the glass before it had reached a hundred feet in depth. The Edison Company then produced a lamp in which the platinum wires were soldered to copper wires in a glass cavity, and filled in with resin, so that copper wires, about No. 30 in size, projected from the lamp for our attachment. I coiled the copper wires spirally, and soldered their ends to the ends of the heavy wires of the cable, separating them by a small block of pine wood; this gave some freedom of motion without danger of cutting or breaking the wires. A paper mould was placed round the joint, and filled with warm "gulloot." When this had cooled, it was wrapped with insulation tape and served tightly with twine. This was again covered with gulloot, then tape, and finally with melted gutta percha; and, when the gutta percha had cooled, its entire surface was seared over with a hot iron, to make sure of filling any cracks or holes it might contain. The lamp was then lowered into the sea, about seven hundred and fifty feet of cable being paid out, without any indication of failure. To ascertain if the lamp was lighted at all times, we substituted a lamp for the cut-out plug in the deep sea circuit. This brought both lamps in the same circuit, which caused them to glow at about a cherry red instead of a white light; and had any accident happened to break the lamp in the water, or to cause a leak, our upper lamp would have immediately sprung into incandescent whiteness."

On an Induction Magnetic Compass.—We alluded in a recent note to a new form of compass designed by M. Mascart. The following description of this compass is taken from the *Phil. Mag.* for this month:—Weber's inductometer enables us to determine the magnetic inclination by measuring the currents induced in a conducting frame, which is first turned through an angle of 180deg. about a horizontal axis starting from the horizontal plane, and then about a vertical axis starting from a plane perpendicular to the magnetic meridian. Such is the method in use in many observatories If the apparatus is so arranged that the axis of rotation of the frame is in any direction in the magnetic meridian, and if we seek by trial for two directions such that for an angular rotation of 180deg. the needle of the galvanometer experiences equal impulses in opposite directions, the line bisecting these two directions will give the position of equilibrium of a dipping-needle. This second method has recently been proposed by M. Wild. It is clear that the induced currents must be zero, when the axis of rotation of the frame is exactly parallel to the direction of the magnetic force. With the ordinary method of observation, which consists in turning the frame through 180deg., we obtain the same degree of exactitude as by measuring the angles of throw; but the *null method* enables us to dispense with any measurement of the throw, as well as any regulation of the initial and final positions of the movable frame. We have in this the advantage that, if we are near the wished-for direction, we may, by alternate movements of the frame of the same period as that of the oscillations of the needle, multiply the angles of throw, and thus demonstrate the existence of a deflection which in itself would have been inappreciable. The accuracy of the method is thus considerably increased; we may then greatly diminish the dimensions of the rotary frame, and it is convenient to use a galvanoscope of suitable resistance to which the maximum of sensitiveness is imparted. I have for some years tried to realise this experiment by means of an apparatus which can be readily carried about. It consists of an azimuthal circle on which moves an arrangement which supports a ring movable about a horizontal axis; the angle which this ring makes with the vertical is measured by a vertical circle; the frame, which is only 0·12 metre in diameter, is supported by the ring and can turn about an axis perpendicular to that of the ring. The dimensions of the instrument do not exceed those of an ordinary dip-needle. By a series of systematic trials we can first find the angle of the ring at right angles to the magnetic meridian; by a second series the axis of rotation of the frame is brought into the direction of the dipping-needle. With the inversions necessary to eliminate the errors of reading, the entire observation does not take half an hour; this is scarcely the time required to determine the inclination by the dipping-needle. As regards the accuracy of the results, it does not appear to be less than that of the dip-circles, the handling of which is so delicate. I will give, as an instance, some observations recently obtained by M. Morneaux at the observatory of the Parc Saint-Maur.

| | Inclination. | |
|---|---|---|
| | Induction apparatus. | Brunner's compass. |
| | ° ′ | ° ′ |
| September 18, 1883 ..... | 65 21 | ..... 65 20·7 |
| „ 29, „ ..... | 65 24 | ..... 65 23·8 |
| October 16, „ ..... | 65 20 | ..... 65 23·4 |
| „ 26, „ ..... | 65 22 | ..... 65 18·9 |
| November 7, „ ..... | 65 19·5 | ..... 65 17·5 |

If it be remembered that the observations were not made simultaneously, and that the results given by dip-needles of different patterns, observed at the same time, scarcely agree better, it will be seen that it is difficult to give any good reason for preferring one method to the other. The reading for the magnetic meridian is sufficiently accurate to allow us to determine the declination to within a minute; hence by adding a telescope we get a true magnetic theodolite. I may add that the dimensions of the frame may be still further diminished by introducing soft iron. The induced currents are thus made far stronger without any inconvenience, for the changes of magnetisation would still be null for any rotation about the direction of the terrestrial force.

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 151.)

**Electrolytic Separation of Hydrogen.**—H. Electro-chemical equivalent = 1. A monad cation. The only known gaseous metal. Is very readily separated; it is set free in a very large number of cases where water, acids, or other salts of hydrogen are electrolysed. In some cases it is set free by direct action, as when zinc or any other metal more electro-positive than hydrogen is immersed in the above liquids. In other cases it is liberated by "secondary action," as when those metals more electro-positive than hydrogen are electro-deposited from aqueous or acid solutions, and subsequently decompose the liquid by simple contact.

It is separated by all the electrolytic processes. Its liberation and subsequent spontaneous ignition when potassium is placed upon water is one of the most familiar and striking experiments of electro-chemistry. Magnesium, and especially its amalgam with mercury, decomposes water, setting free hydrogen. The same metal also liberates hydrogen from a great variety of saline solutions. Nearly all the readily oxidable metals decompose acidulated water; and the instances are so numerous that to specify all of them is quite unnecessary. According to H. St. Claire Deville, silver evolves hydrogen rapidly from aqueous hydriodic acid; and even silver, gold, and platinum, when in a finely divided state, liberate hydrogen from a hot concentrated solution of potassic cyanide.

I have observed the following cases relating to separation of the gas by magnesium. That metal did not evolve hydrogen by simple immersion in dilute hydrofluoric acid, and only a little in an aqueous solution of potassic chloride; but evolved it freely in a mixture of the two liquids. Similarly with the same acid and a solution of chlorate of potassium. It did not evolve the gas in a mixture of the same acid and a solution of potassic perchlorate. It set free hydrogen from a mixture of that acid and a solution of potassic bromide; but not from either alone. Similarly with magnesium in hydrofluoric acid mixed with solution of potassic iodide; but not with that acid when in admixture with solution of potassic iodate. It set free hydrogen from a mixture of that acid and solution of potassic sulphate; but not from either liquid alone. Probably the absence of gas was due, in some of these cases, either to the formation of a film of magnesic fluoride or suboxide upon the surface of the metal, and the insolubility of that salt in the particular liquid.

Some anhydrous hydrogen acids yield hydrogen readily by electrolysis; others do not. With platinum electrodes and a separate current from ten Smee cells, anhydrous hydrofluoric acid at 0°C. was freely decomposed; but anhydrous hydrochloric acid, liquefied by great pressure at 0°C., scarcely conducted at all, and evolved no visible gas.

Nearly all aqueous acids yield hydrogen at the cathode by the separate current process. This accords with G. Wiedemann's observation, that mixed liquids are more easily electrolysed than unmixed ones. According to Bourgoin, by electrolysis with platinum electrodes of distilled water containing pure sulphuric acid, the hydrogen and oxygen obtained are probably not results of an action of the current upon the water, nor of liberated electrolytic products acting upon the water, but of direct decomposition of a hydrate of sulphuric acid. Concentrated nitric acid does not liberate hydrogen by electrolysis, the hydrogen being absorbed. Aqueous solutions of alkalis frequently yield hydrogen at the cathode. The electrolytic behaviour of each of the individual acids, salts, and alkalies, with regard to separation of hydrogen, &c., will be more fully described under the heading of the respective substances.

In consequence partly of the very frequent simultaneous deposition of hydrogen with other metals, those metals often contain that gas. It has been observed conspicuously in deposited palladium, and, to a less extent, in iron, cobalt, nickel, copper, and tin, and it has been stated that the explosive variety of deposited antimony contains hydrogen; but, according to E. Pfeifer, "explosive antimony" contains no free hydrogen (*Jour. Chem. Soc.*, Vol. XLII., 1882, p. 467). Much, however, depends, in all these cases, upon the kind of solution employed. I have several times observed that the steel blade of a knife which has been used as a cathode for a short time, either in a dilute acid, or in an alkaline liquid, becomes very brittle. Other investigators have also noticed that the simple immersion of iron in a dilute acid greatly reduces its tenacity; and it is not improbable that steam boilers are sometimes weakened by their decomposing the water and absorbing the hydrogen. It has been stated by Böttyer that if a piece of palladium, cobalt, nickel, or tin, has a wire of aluminium twisted round it, and is then immersed during a few minutes in a dilute acid, it absorbs sufficient hydrogen to exert a slightly reducing action upon a solution of potassic ferricyanide, also that a plate of palladium, previously coated with palladium black, absorbs the gas more rapidly, and when taken from the liquid and dried quickly between porous paper becomes red hot in the air in a few seconds.

For the absorption of hydroden by platinum in electrolysis, see *Jour. Chem. Soc.*, 1877, Part II., p. 161, and for the deposition of hydrogen on both electrodes *see ibid*, Part I., p. 678.

**Separation of Oxygen.**—O. Electro-chemical equivalent $= \frac{16}{2} = 8$. A dyad anion. It is much less frequently or readily obtained than hydrogen by electrolysis, also less easily than the least oxidable metals. It is not separated by either of the electrolytic methods, except those in which a separate current is employed. To obtain it requires not only a separate source of current, but also an anode and liquid not easily oxidised. It is usually obtained by passing a current by means of platinum plates through a cooled mixture of one volume of sulphuric acid, and three to five volumes of pure water. The gas thus obtained is partly in the state of ozone, which may be detected by its odour. Numerous other mixtures of water with some acid, alkali, or salt, to render the mixture conducting, might be employed for obtaining it, but in all cases the anode must be a non-corrodible one. The electrolysis of various substances such as fused oxides, &c., which yield oxygen, will be described in their appropriate places.

**Electrolysis of Water.**—$H_2O$. Molecular weight = 18. F. Kohlrausch has shown (*Dingler's Polytechnik Journal*, Vol. 222, p. 283) that perfectly pure water is practically a non-conductor of the voltaic current (and probably not an electrolyte), and that on the addition of the least trace of impurity its conduction-resistance is greatly diminished.

Pure water is rapidly decomposed by simple immersion or contact of either of the alkali metals, less rapidly by aluminium amalgam and by magnesium, and slowly by the ordinary base metals, in each case by oxidation of the immersed metal. Magnesium amalgam containing one half a per cent. of magnesium decomposes water with violence, and more rapidly than sodium amalgam containing twice that percentage of sodium (Cailletet, Watts' *Dic. of Chem.*, Vol. VI., p. 816)). An amalgam of aluminium and mercury decomposes water at ordinary temperature (A. Cossa, Watts' *Dic. of Chem.*, Vol. VII., p. 54). Alloys of aluminium and gallium decompose water readily, setting free much hydrogen and nearly the whole of the gallium as liquid metal (Lecoq de Boisbaudran., *Chem. News*, Vol. XXXVII., p. 274). Finely divided iron slowly decomposes boiling water, and sets free hydrogen (E. Ramann, *Jour. Chem. Soc.*, Vol. XL., 1881, p. 879). Water containing certain acids is decomposed more rapidly; boracic acid, cyanide of mercury, sugar, or gum dissolved in it have but little effect. The decomposition of water containing sulphuric acid, by means of zinc, is a common mode of obtaining hydrogen. Iron filings wetted with water, and exposed to the air or nitrogen at 60° F., induce the formation of ammonia (Berzelius).

Gladstone and Tribe state that pure water may be decomposed by a "copper-zinc couple," also by iron or lead which has been previously coated electrolytically with spongy copper. At 0°C. the decomposition of water by a zinc-copper couple is nearly *nil;* but at 100°C. it is very great (*Jour. Chem. Soc.*,

Digitized by Google

Vol. XXXV., 1879, p. 572). With a magnesium platinum couple the decomposition is vigorous, even in cold water (*Ibid*, p. 576).

According to D. Tommasi, water is not decomposed by a separate current from a single zinc-carbon or zinc-copper element if the electrodes are of platinum; but if the anode is a metal—copper, for instance—which, under the influence of that current, can unite with oxygen, the water is decomposed (*Jour. Chem. Soc.*, Vol. XLII., 1882, pp. 134 and 353).

The usual mode of electrolysing water is by previously mixing sulphuric acid freely with it, and passing a separate current through the mixture by means of platinum electrodes; by this method its oxygen as well as its hydrogen is obtained, and a small quantity of the former gas is absorbed by the water. The oxygen contains a small proportion (but not more than $\frac{1}{250}$ part of its weight) of ozone.

Janeczek considers that in the electrolysis of pure water, hydrogen at the cathode and hydric peroxide at the anode are the proximate resultants, and that the peroxide is resolved into water and oxygen (*Jour. Chem. Soc.*, 1876, Part I., p. 182).

Bouvet electrolysed water under a pressure of several hundred atmospheres. He found that the amount of water decomposed by a given quantity of current was independent of the pressure (*Jour. Chem. Soc.*, Vol. XXXVI., 1879, p. 293).

Water containing atmospheric air yields ammonia at the cathode, and nitric acid at the anode (H. Davy).

---

## THE THEORY OF DYNAMO-ELECTRIC MACHINES.

Professor Clausius, F.R.S., of Bonn, stands perhaps at the head of living authorities on the theory of electricity; and anything coming from him on that subject is sure to contain much that is both of interest and value. This is especially the case when he applies himself to deduce the theoretical laws of an apparatus possessing a wide practical application. This is what he has done (in a paper lately read before the Swiss "Naturforschender Gesellschaft") in the case of the Dynamo-electric machine, which, as he himself observes, has altogether outstripped theory in its progress; so that, as in the case of the steam engine, it is only when it has become a regular product of industry that men have found time to ask what are the theoretical laws by which its working is governed. These laws it is the purpose of his paper to examine and develop; and we need make no apology for presenting to our readers in the following pages the substance of his inquiry.

### 1. *Essential Features of the Dynamo Machine.*

Whilst varying greatly in form, dynamo machines differ but little in the principles on which they are based. The Gramme and Siemens may be taken as sufficient types of continuous current machines; and even these are so much alike that, as far as their fundamental principles are concerned, they may be included in one and the same investigation.

Such machines consist, first, of a fixed electro-magnet, with large polar surfaces, or of a series of such magnets, having their equivalent poles connected by pieces of iron. For the purposes of this inquiry the difference is immaterial; and hereafter, when the fixed electro-magnet is spoken of, it will be understood as indicating either one or several.

In the space between the poles of the fixed electro-magnet is placed the rotating electro-magnet. This in the Gramme machine has the annular form suggested by Pacinotti, and consists of a ring of iron (either built up of wires or in a solid piece) round which the conducting wires are wound in a spiral. In the Siemens machine it takes the form of a drum, with the conducting wires wound round the outside. These outer and inner members must be treated apart, and may be designated respectively as the rotating coil and the iron core of the rotating coil. For the first the power of rotating is a necessity; for the second it is not so, and in fact the action would be improved if it were kept at rest, which, however, is in practice very difficult.

The rotating coil is divided into many parts, which, however, are all in communication, the end of each being connected to the beginning of the next by a strip of metal. These strips lie so close together (without, however, being in metallic contact) that they form a cylinder, which rotates with the coil. Over these strips slide two contact springs, forming the beginning and end of the conducting wire which surrounds the coil of the fixed magnet. These contact springs divide the rotating coil, in any one position, into two halves, and the general system of wires into two branches, so that the current which passes through the rotating coil from one contact spring to the other is split into two halves. These separate at the first contact spring, pass round the coil in opposite directions, and meet again at the other.

The iron core of the rotating coil is magnetised in two ways. In the first place it comes close to the poles of the fixed electro-magnet, though without actually touching them, and is thus magnetised by ordinary induction, in such a way that each pole of the fixed magnet has the opposite pole of the core turned towards it, or, for brevity's sake, we may say that the two axes lie in the opposite directions. Secondly, the coil is magnetised by the current passing through the rotating coil from one contact spring to the other. The springs are so arranged that the magnetic axis for the second kind of magnetism is at right angles to the axis for the first. Hence we have a resultant magnetism whose axis lies obliquely between these two directions. If the core rotates, its poles retain a fixed position in space, while continually altering their position within the core.

The induction going on in the rotating coil is of a threefold character. First, the fixed magnet induces magnetism in the rotating one. Secondly, the magnetised iron core, whose axis remains fixed in space, induces magnetism in the coil rotating round it. Thirdly, the current passing within the coil itself, which changes its direction as the different parts come in contact with the springs, has to some extent at least a magnetic influence on the coil.

### 2. *Law of Induction.*

To investigate this law, we must examine more closely what we mean by the current and conducting wires. The coils, whether fixed or rotating, consist of a great number of turns, which lie so close to each other that for any one turn, or any connected group of turns, it makes very little difference, if we suppose the end to be joined to its own beginning, instead of to the beginning of the next turn or group of turns. We may thus treat both the fixed and rotating wires as a system of closed circuits. Moreover, as concerns the magnetisation of the masses of iron employed, it is known that the electro-dynamic action of a magnet may be explained by supposing that a number of indefinitely small closed electric currents are going on inside it. We have thus only to do with the action of closed currents on closed circuits. This greatly simplifies the investigation, and removes all the causes of doubt which prevail as to the working of open currents in connection with open circuits.

The law of induction is arrived at very simply by considering the action of the electro-dynamic potential of the actual current on a wire through which a unit current is passing. Let there be a system of closed currents, circulating in wires $s$, $s_1$, $s_2$, &c., with intensities $i$, $i_1$, $i_2$, &c.; and let there be another closed wire $\sigma$, which has a unit current passing through it. Let $ds$ be any element of one of the wires $s, s_1$, &c., and $d\sigma$ an element of the current $\sigma$; let $(s\,\sigma)$ represent the angle between the directions of the two elements, and $v$ their distance apart; then the potential W of the given system of currents on the current of intensity 1 within the wire $\sigma$, is given by the equation—

$$W = \iint \frac{i \cos (s\,\sigma)}{v}\, ds\, d\sigma \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where the first integral is taken over all the wires $s$, $s_1$, &c., and the second over the wire $\sigma$.

It is here assumed that the intensity of the current is

Digitized by Google

measured in electro-dynamic or electro-magnetic units. If electro-static units are employed the expression must be divided by $K^2$, where K is the critical velocity for electricity.

If any motion takes place in the wires, with a consequent change in the intensities $i, i_1$, &c., then an electromotive force $e$ will be induced in the wire $\sigma$, of which the value is given by the simple equation ($t$ being the time)

$$e = -\frac{dW}{dt}.$$

3. *Application of the Equation to the Rotating Coil.*

We have now to apply the above equation to the electromotive force induced in the rotating coil, in consequence of its motion, by the current in the rest of the conductors and by the magnets. We may choose any one of the parts into which the coil is subdivided, and take it to represent the wire $\sigma$.

If we follow this part through a complete revolution, we shall see it pass through a series of changes in position back to its position at starting, so that the final and initial values of W are the same. It follows that, if the direction in which the E.M.F. is reckoned positive remains the same in this part of the coil, the E.M.F. induced must be positive at one part of a revolution, negative in another, and that the sum of the whole must be zero; but in reality it is otherwise. As described above, the whole rotating coil, in each position, is divided by the contact springs into two halves, forming different paths for the current between those springs. Hence the direction in which the E.M.F. is taken as positive is not constant during the whole revolution, but is different at each instant in the two halves, as is obvious if we reflect that the current may take either direction to pass from one spring to the other. Hence for any particular member of the coil the direction to be taken as positive changes after every semi-revolution at the instant when this portion slides under a contact spring, and so passes from one division of the coil to the other. If the springs are properly arranged, these are also the places where the induced E.M.F. changes its direction, so that the sign of this induced E.M.F. remains unaltered.

As the inducing action is the same during both halves of the revolution, it is sufficient, in order to determine the mean E.M.F., if we consider only one half-revolution, during which the member of the coil moves from one spring to the other. At time $t'$, when this begins, let W' be the value of W, and let W'' be its value at time $(t' + \frac{1}{2}\tau)$, $\tau$ being the time of a revolution: then equation (2) gives us, to determine the mean E.M.F., the following equation:—

$$\frac{1}{\frac{1}{2}\tau}\int_{t'}^{t'+\frac{1}{2}\tau} e\,dt = -\frac{1}{\frac{1}{2}\tau}\int_{t'}^{t'+\frac{1}{2}\tau}\frac{dW}{dt}dt = \frac{1}{\frac{1}{2}\tau}(W' - W'').$$

From this expression, which applies only to one member of the rotating coil, the expression for the whole coil is obtained by simply multiplying by the number of members which must be taken into account. To fix this number we must remember that the induced E.M.F.'s in the two halves of the coil must not both be taken, because the two halves do not lie one beyond the other in the same circuit, but form two branch circuits lying near each other. In other words, if $n$ is the total number of separate portions of the coil, we must multiply the mean E.M.F. for one portion by $\frac{n}{2}$, not $n$, in order to obtain the total E.M.F. for the whole coil. If we designate this total by $E_1$, we obtain

$$E_1 = \frac{n}{\tau}(W' - W'') \quad . \quad . \quad . \quad . \quad . \quad (4).$$

It is better to substitute for the time of a revolution the number of revolutions per second. If $v$ is this number we have

$$v = \frac{1}{\tau} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5),$$

and equation (4) becomes

$$E_1 = n(W' - W'')v \quad . \quad . \quad . \quad . \quad (6).$$

4. *Reflex Action of the Moving on the Fixed Wires.*

Hitherto we have considered only the E.M.F. induced in the moving wires by the current in the fixed coil, and by the magnetism in the masses of iron. We have now to see whether the current in the moving coil induces an E.M.F. in the fixed coil.

We again confine ourselves to a single member of the moving wires (or rotating coil) which we designate $\sigma$. Let $j$ be the current passing through it, and changing its direction twice in each complete revolution. Let us now consider a unit current to be passing through the fixed wire $s$, and form the electro-dynamical potential of $\sigma$ with regard to $s$, which we will call $\Omega$. This will be expressed in the same way as in equation (1), as below:—

$$\Omega = \iint \frac{j\cos(s\sigma)}{v}\,ds\,d\sigma.$$

Hence we may express the E.M.F. $\epsilon$, induced at time $t$ in the fixed wire, by the following equation, corresponding to (2):—

$$\epsilon = -\frac{d\Omega}{dt}.$$

To obtain the mean E.M.F. we must integrate $\epsilon$ with reference to time, and then divide the integral by $\tau$, the time of a revolution. As the positive direction of the E.M.F. in the fixed coil does not alter, we have to integrate in this case over the whole interval from $t'$ to $t' + \tau$, and we obtain

$$\frac{1}{\tau}\int_{t'}^{t'+\tau}\epsilon\,dt = \frac{1}{\tau}\int_{t'}^{t'+\tau}\frac{d\Omega}{dt}dt = \frac{1}{\tau}(\Omega' - \Omega''),$$

where $\Omega'$ is the initial, and $\Omega''$ the final value of $\Omega$ during one revolution. But the position of the member of the rotating coil, and the direction of the current in it, are the same at the end of a revolution as at the beginning; hence $\Omega''$ must be equal to $\Omega$, and therefore the value of the integral is zero. The same holds for all other portions of the rotating coil, and thus we have the result that *there is no induced E.M.F. in the fixed coil.* In point of fact, the forces induced by the motion and by the changes of direction cancel each other.

(TO BE CONTINUED.)

## THE EVOLUTION OF DYNAMO MACHINES.—IV.

BY JOHN T. SPRAGUE.

(CONTINUED FROM PAGE 58.)

31. Although there is no striking difference of system in the various forms of field magnets, there is a defined line of development of functional action which should be clearly traced out. The permanent magnet was the starting point,

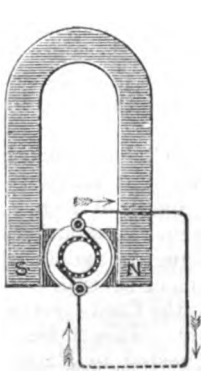

FIG. 17.

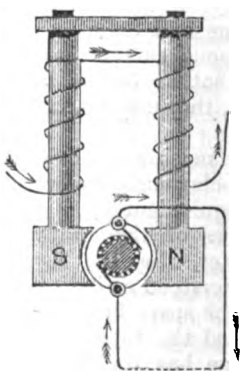

FIG. 18.

Fig. 17.—Magneto Machine, with Ring Armature.
Fig. 18.—Externally Excited Electro-magnetic Machine.

and at first the electro-magnet merely replaced it, as shown by Fig. 17, which is a diagram of a simple magneto-machine with a ring armature, and Fig. 18, which is that of an externally excited electro-magnetic machine, the current for

Digitized by Google

which may be derived from a distinct machine, as in the Wilde machine, and in the Grammes used for the Jablochkoff candle system of lighting with alternating currents; or from a second armature on a common axis, as in Ladd's machines, and some of the early Gramme machines, or from a distinct wire upon the same armature as that supplying the circuit.

32. There is no essential difference between these, so long as a uniform current passes in the field magnet of Fig. 18, and at first the whole object of these machines was to merely replace the ordinary batteries. It is from this primary function that the dynamo machine has developed into an agent of much greater and more varied powers than the battery. Even these primal, simple forms have the germ of the higher functions in them, because while a battery generates a definite electromotive force, dependent on the chemical actions within it, we have here an E.M.F. variable at will, because in these machines *E.M.F. is proportional to speed.*

33. This ratio is, however, maintained only within certain limits; it would hold good if iron had an infinite capacity for magnetism, and received magnetism instantly. As it possesses neither of these qualities, the ratio is a constantly lowering one, which at length reaches a limit, due to the iron of the armature having reached a stage at which its magnetism cannot be increased, and at which increased speed may even reduce the magnetic charge.

34. This is plainly shown by Deprez's "characteristic curve," as shown in Fig. 19. Such a diagram serves the same purposes as the indicator diagram of a steam engine. In this case the line O V is the scale of *speed*, and the line O A the line of *current*. Now, if E.M.F. were truly proportional to speed the resultant of these two functions would be a straight line rising diagonally *ad infinitum* as O I. But the actual result is a curve as O C E, which is truly the indication of the magnetic charge of the iron of the armature.

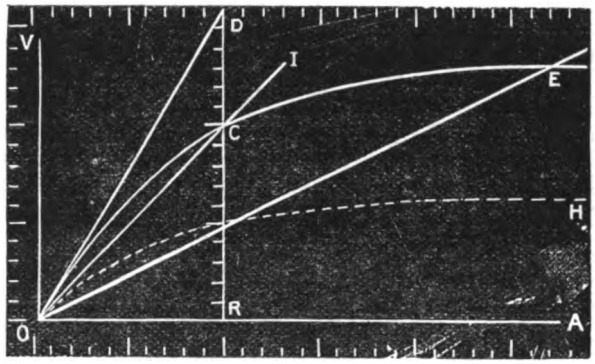

FIG. 19.—Deprez's Characteristic Curve.

35. But Fig. 19 has another meaning. E.M.F. varies *as the strength of the magnetic field*, therefore we get a step of evolution in Fig. 18 from the permanent magnet, because we can vary the strength of the field according to the current sent into the electro-magnet. But here we have exactly the same limiting agency, the strength of field does not vary *as the current*, but only as this, subject to just such a reducing ratio as that of the above curve, caused by the lowering increment of magnetic capacity as the field magnet approaches its limit of magnetic charge.

36. Therefore the line O V, in Fig. 19, may represent the currents passing in the field magnets of Fig. 18, and the curve O C E will then represent the current generated in the armature for a fixed speed. The curve for any other speed may be constructed by making the lengths of the ordinates hold the ratio of the speeds; the dotted curve is that due to a speed half that of O C E.

The changes effected in the line thus generated by each individual machine indicate the line of evolution in which modifications have been effected or should be aimed at.

37. Such a diagram shows also the resistance corresponding to any conditions. On a tangent galvanometer the current is proportional to the tangent of the angle of deflection, and with a constant E.M.F. the resistance is proportional to the co-tangent of the angle, a fact which I first recognised and applied to galvanometers graduated to read resistance in ohms. So in this diagram the resistance is proportional to the angle formed at any point in the curve. At the distance O R (which is here taken as the unit length of the two lines O V, O A) a perpendicular is erected and graduated, the length O R being one ohm, if the same length is an ampere on O A and a volt on O V, or a speed or current giving one volt E.M.F.; thus the line C R is the tangent of the angle C O A defined by the point C representing one ampere of current on the curve, and marks the relations of one volt, one ampere, and one ohm.

38. A battery generates a uniform E.M.F. irrespective of its external circuit. This, like the laws of speed and current just referred to, relates only to an imaginary perfect battery, actual batteries, even the Daniell, being subject to variations; but for present purposes we must assume perfect fulfilment of theoretical principles. Such a battery, therefore, generates current according to Ohm's law $C = \frac{E}{R}$, and machines with constant fields, as Figs. 17 and 18, do the same, subject to the effect of a small reaction of the armature in displacing the field poles and weakening them, which it is unnecessary to do more than incidentally mention. These machines are therefore strictly comparable to batteries, and generate current upon the same law.

39. They have, however, the power, which batteries do not possess, of modifying the E.M.F. at will—1, by variation of speed, which is a mechanical mode; and 2, by varying the strength of the field, which is an electrical action. This may be done in the electro-magnet by varying the current, and in the permanent magnet by applying or approaching masses of iron, which will take up part of the field of force, and so weaken that in which the armature coil rotates. This plan, long used in the medical magneto machines, has been proposed and patented for large dynamos, and it might be operated either by an attendant or automatically.

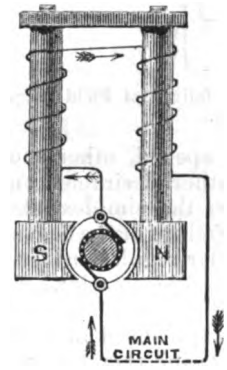

FIG. 20.

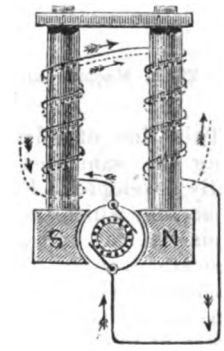

FIG. 21.

Fig. 20.—Series Wound Dynamo.
Fig. 21.—Series Dynamo Externally Excited.

40. The next stage of evolution was the causing the external circuit itself to strengthen or weaken the field magnets according to its own requirements. As the armature generates a current variable with the external resistance, if the field magnet is fed by this varying current a new element of variation is attained, and thus we have the *series* machine Fig. 20, and the combined *series and external system* of Fig. 21.

The external source in Fig. 21 might be either a separate machine, in which case it would be entirely independent of the varying circuit, and would always supply a minimum magnetism to the field; or it might be a second armature or a second wire, in which case it would be re-acted upon by the varying field magnetism due to the series circuit.

41. In either case Fig. 21 would be less subject than Fig. 20 to a difficulty in setting up a sufficient current in the field magnet to start the work, especially against a large resistance. This is one objection to series machines, and another is their liability to reversal when doing any work which sets up a counter E.M.F., as in the case of electrolysis. This is met by using an arrangement to short circuit the armature until a certain speed is attained and a current developed, when the external circuit is automatically thrown in.

Digitized by Google

The line O in Fig. 19, which is a tangent to the commencement of the curve, indicates the condition of resistance at which a series machine will fail to generate current.

In these machines the E.M.F. rises much more rapidly than the speed, and the relations are much too complicated to be expressed in any moderately simple formula.

42. The advantage gained over the battery, and the analogous mechanical source are readily manifested in electro-metallurgy. If the E.M.F. and supply is adequate to the plating a large vat full of objects upon which definite rate of current is required, any variation of the surface necessitates a controlling resistance to be employed. Thus, if the vat is intended to work with 100 objects each offering 1 ohm resistance and requiring ·5 ampere current, we have a total cell R = ·01, which, on the old law of equal resistances, means also a battery or machine R of ·01, or a total R = ·02, and total current = 50 amperes. To produce this the source must have E.M.F. = 10 volts. Now, with a single object in action we have E = 10 ÷ R = 1·01, giving a current of 10 amperes instead of ·5. But with the series machine the reduced current might immediately reduce the magnetism and resulting E.M.F. to volt ·5, and thus only the required current would be supplied.

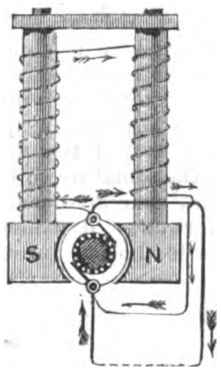

FIG. 22.—Shunt Machine which prevents failure of Field Magnets and their reversal.

43. This line of advance once opened, other modes of attaining the same results and other desirable conditions gradually developed. Fig. 22 shows the simplest stage, the shunt machine which prevents the failure of the field magnets and their reversal, and gives a similar regulation for successive resistances in series, which the series machine gives for those acting as shunts, *i.e.*, in multiple arc. As the introduction of external resistance alters the shunt ratio it sends more current into the field magnet, and therefore generates a higher E.M.F. necessary to send the current through the increased resistance.

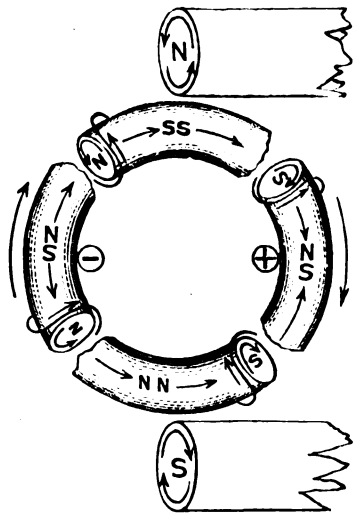
## THE PHYSICAL THEORY OF THE GRAMME MACHINE.

BY DESMOND G. FITZ-GERALD.

By the aid of the law of Lenz, of the accompanying diagram, and of a few observations which I purpose now to make on the laws of magneto-electric induction, the theory of dynamo machines of the Gramme type will, I think, be rendered perfectly clear to those at whose request I am writing this short explanation, as well as to the majority of your readers.

We have first to note that, according to Lenz's law, a current (voltaic or amperian) induces in neighbouring conductors *inverse currents* whilst it is augmenting or approaching, and *direct currents* whilst it is diminishing or receding. (By "inverse" is meant: "in the direction opposite to that of the inducing current"; and by "direct" "in the same direction as this current.")

Next, we have to give our attention to a point which is by no means generally understood, even by the average electrical *savants* (whose knowledge of the magnetic *circuit* is generally about equal to his knowledge of the electrostatic circuit, i. e. *nil*). This point is that the (magneto-electric) inductive effect of a magnet, or magnetised core, upon a coil of wire surrounding it is independent of the absolute "magnetic potential," or external attractive force, of the portion of the magnet or core which is surrounded by the wire. Thus, in the construction of an induction-coil, it is a mistake to coil the greater portion of the secondary wire in the vicinity of the poles or ends of the core, under the impression that "the magnetism is there strongest"; and, as a matter of fact, a better result will be obtained by coiling the wire mainly in proximity to the centre or "neutral point" of the interior electro-magnet; and a still better result by circuiting the latter with an armature, so that the externally-exhibited polarity may disappear. Again, to give another example, if in a Gramme dynamo-machine we circuit through a galvanometer the coils of wire surrounding that portion of the armature marked S S, or that portion marked N N, in the diagram below, and if we then excite the external field magnet, our galvanometer will show that this portion of the core, where the external polarity is strongest, has *no inductive effect* upon the coils. But if in similar manner we take the coils of wire surrrounding that portion of the ring in proximity to the — collector and marked $\frac{N}{S}$ (or those surrounding the analogous opposite portion of the ring in proximity to the + collector), we obtain the maximum inductive effect, although the "magnetic potential" is here a mininum. The mischievous explanation of magneto-electric inductions by the "cutting of lines of force" (instead of by Lenz's law) has much to do with the mystification which is prevalent in relation to these and similar phenomena.



Thirdly, we have to consider that the amperian currents in a magnet (to which the magneto-electric effects are attributable) are strongest in those portions of the magnetic circuit where their mutual attractions are most readily satisfied, *i.e.*, in those portions where the external force is a minimum. These currents vary as the "magnetic inertia," or as the *difference* of magnetic potential divided by the resistance at that portion of the magnetic circuit where they are located. The amperian currents in planes perpendicular to the axis of the ring *diminish*, therefore, as we approach S S or N N, where the difference of magnetic potential is *nil*, and the resistance of the magnetic circuit is greatest (*i.e.*, where the facilities are least for the completion by induction of the circle of attraction between amperian currents in the same direction). And these amperian currents increase in strength as we approach either of the two points $\left(\frac{N}{S}\right)$ on the median line; for here there is a difference of polarity in the direction of the ring (as is shown by a magnetised needle placing itself parallel to this direction), and the resistance in the magnetic circuit is least, since it is constituted by all the paths of induction originating in the quadrant S N and terminating in the quadrant N S.

Digitized by Google

Presuming it is clearly understood that at the points N N, S S there is no magnetism (*i.e.*, attraction of amperian currents) *in the direction of the ring*; or that we may correctly say that the two similar opposed poles (N N or S S) exactly neutralise each other, let us suppose the ring to be rotating in the direction indicated by the external arrows, and let us consider the magneto-electric inductive action of the amperian currents upon one turn of wire in each quadrant of the ring. Taking a section through the ring in the lower left-hand quadrant, we expose to view a north pole in the uppermost portion of this section. The amperian current will here be in the direction opposite to that of the hands of a watch; and this current will evidently be *augmenting*, since it was *nil* at N N, and will be a maximum at $\frac{N}{S}$. The current induced in the wire will therefore be *inverse*, or its direction will be opposite to that of the amperian current; and, by reason of the direction in which the wire is wound, the electromotive force acting in the coils on this quadrant will maintain a *minus* potential in the collector marked — in contact with the coils on the median line.

Again, taking a section through the ring in the upper left-hand quadrant, a second north pole will be exposed in the uppermost portion of the section. But the amperian current will here be diminishing; since it was a maximum at $\frac{N}{S}$, and will be a minimum at S S. The current induced in the surrounding wire will therefore be *direct*; and its general direction will be from below upwards, or such that electricity will be abstracted from the collector marked —.

It will further be seen that in the right-hand upper quadrant the current induced in the turns of wire will be *inverse*, and that its general direction will be from above downwards, so that it will maintain a plus potential in the collector marked + on the median line. Lastly, in the remaining quadrant the induced current will be direct; its general direction will be from below upwards, and it will maintain a positive potential in, or tend to escape from, the collector marked +.

I need say nothing further in explanation of the inductive action to which the effective current is due in dynamo-machines of the Gramme type. On another occasion I shall refer to the erroneous explanations which hitherto have been put forward, and which have had the effect of completely obscuring the means whereby a fundamental improvement in machines of this type may be effected.

## STUDENTS' COLUMNS.

The following proofs may be interesting to many students:

I. Proof of Wheatstone's bridge.

Let A, B, C, D, and E be the resistances of the five conductors of the bridge; $a$, $b$, $c$, $d$, and $e$ the currents in each respectively; and O, P, Q, and R the potential at those points.

By Kirchoff's equation

$$a = d + e, \text{ and } b = c - e.$$

$$\text{Now, } a = \frac{O - P}{A}, b = \frac{O - Q}{B}, c = \frac{Q - R}{C}, \text{ and } d = \frac{P - R}{D},$$

$$\therefore \frac{O - P}{A} = \frac{P - R}{D} + e \ (1),$$

$$\text{and} \qquad \frac{O - Q}{B} = \frac{Q - R}{C} - e \ (2).$$

Dividing (1) by (2) we have

$$\frac{B(O - P)}{A(O - Q)} = \frac{\frac{P - R}{D} + e}{\frac{Q - R}{C} - e} = \frac{C}{D} \cdot \frac{(P - R) + De}{(Q - R) - Ce}.$$

Now when $e = o$, or there is no current in E, P = Q,

$$\therefore \frac{B}{A} = \frac{C}{D},$$

$$\text{or} \qquad D = \frac{A}{B} . C.$$

Q. E. D.

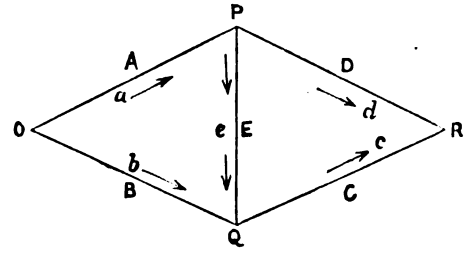


Fig. 1.—Wheatstone Bridge.

II. Proof of Mance's method of finding the internal resistance of a battery.

Let, as before, A, B, C, D, E, and F represent the resistances of those parts, and $a$, $b$, $c$, $d$, $e$, and $f$ the currents through them.

Let R be greater than P, and the currents flow in the direction of the arrows.

By Kirchoff's equations

$$a = d - f \ (1) \qquad b = c - f \ (2)$$
$$d = a + f = c + e \ (3).$$

Dividing (1) by (2) we obtain

$$\frac{a}{b} = \frac{d - f}{c - f}$$

$$\frac{\frac{O - P}{A}}{\frac{Q - O}{B}} = \frac{\frac{P - R}{D} + f}{\frac{R - Q}{C} + f}$$

$$\frac{B(O - P)}{A(Q - O)} = \frac{C\{(P - R) + fD\}}{D\{(R - Q) + fc\}}$$

but from (3)

$$a + f = c + e$$
$$e = a - c + f.$$

Now, for $e$ to remain the same, whether the conductor F be closed or open, in which latter case $f = 0$, $f$ must be 0 in the former.

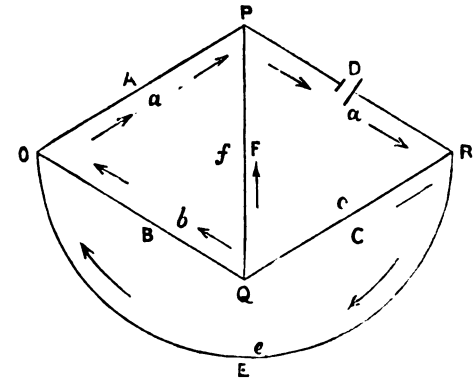

Fig. 2.—Mance's Method.

When $f = 0$ $P = Q = X$;

$$\therefore \frac{(O - X)B}{(X - O)A} = \frac{(X - R)C}{(R - X)D},$$

$$-\frac{(O - X)B}{(O - X)A} = -\frac{(X - R)C}{(X - R)D};$$

$$\therefore \frac{B}{A} = \frac{C}{D};$$

$$\text{or} \qquad D = \frac{A}{B} . C.$$

## NOTICE.

*We should be greatly obliged if Correspondents would address all communications relating to Subscriptions, Advertisements, back numbers of the Paper, and so forth, to the Publisher; and those relating to Articles, Correspondence, or Notes to the Editor. The Editorial and Business Departments of* THE ELECTRICIAN *are entirely separate, and much delay, annoyance, and trouble will be saved if our friends will kindly recollect this.*

# 1883.

"The year is going, let him go;
Ring out the false, ring in the true."

So writes the greatest of living poets; and so, probably, think most right-minded men when they come at the close of a year to think of the trials and struggles, the gains and the losses, the hopes and the fears that have been their lot during the past year, while hope springing "eternal in the human breast" leads them to picture and fancy the New Year as one of brightness, prosperity, and happiness. That those hopes may be realised to each reader of these pages is our heartiest wish.

It has been our custom in the first issue of the year to pass under review the work of the year. This we believe to be a salutary custom. The history may be brief, its lessons not brought out with sufficient clearness, but imperfect as the review may be it has its uses even as a mere record. We can give almost to a day the time of some of the introductions of the applications of electrical science; and the history of the progress of these early years, however scant it may be, will in days to come be read with considerable interest. As a celebrated politician once said, "We are making history;" and without doubt the future history of the world will to a greater or lesser extent be moulded upon the history of scientific progress.

There is no branch of science which at the present time rivals in interest that of "Electricity." Progress in other branches of science has been great and rapid, but at no time in the history of the world has any branch of science made so great or so rapid progress as electrical science during the past five years. The part we have attempted to play during this time has not been altogether unimportant. We have attempted to record faithfully the work being carried on in electrical science. We have at times warned our readers against the jubilant elation of scientific and commercial fanatics, and we have at times endeavoured to raise the spirits of those unduly depressed because failure of all their hopes seemed imminent. It has, of course, been impossible to please everybody. Yet we are fain to hope that our efforts have on the whole been appreciated. If a certain amount of success is a guarantee of appreciation, we ought to be fairly content; but, unlike Alexander, who thought there were no more worlds to conquer, we believe that there are many ignorant minds which are worlds to be conquered and to be profitably enlightened, and we shall therefore not rest satisfied with the present success, but endeavour to deserve a further modicum, and hope twelve months hence to say it has been realised.

A subject of considerable interest has been moving the minds of some well known men of science, and may be appropriately referred to here. It is the diffusion of scientific memoirs. Professor Tait, when reviewing in *Nature* the collected essays of Professor Stokes, strongly urged a more general circulation of papers contributed to societies of repute, and found worthy of a place in the *Transactions* of the societies. Professor Silvanus P. Thompson directs further attention to this suggestion in a letter upon the subject. He dwells at some length on the difficulties which students have to encounter in order to study the papers buried in various *Transactions*. The only practical, or unpractical, suggestion hitherto made is that the papers of various authors should be collected and published in book form. Professor Thompson rather hints to Professor Tait that it would be well so to collect and publish the papers which Professor Tait has contributed to the Royal Society of Edinburgh. We may go further and suggest that Professor Thompson should in the first place set his own house in order. Perhaps he will be found, like Mr. Morris, of Communistic notoriety, ready to criticise others, ready to cry "Do as I tell you," but altogether unwilling to set an example himself. We shall have the rashness to propose a remedy, and we have no doubt have some hard things said of us in return. Probably the hardest will have reference to "everybody for himself." Our views have, however, been put forward at greater or lesser length more than once, though perhaps never so clearly and pointedly as we intend them to be put forward now. Societies are formed for two purposes:—(1) The glorification of a clique, who are conceited enough to think the world cannot progress without their aid, and who are really full of the idea that the use of symbolic or cabalistic letters after their names gives them a decided superiority over the outside public; (2) the desire to disseminate knowledge, and to increase the study of a special subject in every conceivable way. Members and

Digitized by Google

supporters of the latter have intense sympathy with every student. They desire to aid him in his labours, and their talents, aye, and their purses, are never closed to the earnest workers. The members of the former societies are satisfied in their own conceit—a dispensation of nature for which all reasonable men should be thankful. Our remarks will now be confined to those societies which we maintain are the only societies worthy of recognition. The members of these societies meet periodically to hear and to discuss papers contributed by individuals of their body. The papers so read and discussed are usually printed and issued in the form of *Transactions*. Unfortunately these *Transactions* have a very limited circulation, and are published twelve months (more or less) after the paper has been read. Frequently all interest in the paper has then died out, for other and later papers are being considered, and in some subjects twelve months might just as well be twelve years, or centuries. Still, many papers are of permanent value, and here is the worst link in the chain of the societies' work. Men are growing older. A new race of students is continually growing up, an old race dying out. The young student is too often ignorant of the societies' *Transactions*, or too impecunious to join a society, or too enlightened to wait twelve months for what may or what may not contain information he is seeking. The remedy for some of the evils is early publication of the paper. A good example of such publication is seen in that of the Society of Arts. In fact, this society is far and away in advance of younger rivals in almost every detail of its management. If, however, the society is unable to publish its papers at once, is there any reason why the technical journals should not publish them? The reasons adduced against this course in many instances are so unsatisfactory that one is compelled to state they are put forward only to hide the real reasons, which too often will not bear the light of day.

The Press is looked upon as a nuisance, to be tolerated because it is feared; if it were loved it might be a valuable auxiliary. What, for example, was the real reason of the Royal Society in withdrawing a concession allowed to technical journals a few years ago? The printers were then permitted to arrange at a small cost with editors, and to supply proofs of papers a day after the papers were read, or, rather, the proofs were, we believe, posted the same day that the papers were read. Then the editor of, say, a paper devoted to conchology or any other ology would look through the proofs, and, if one was suited for his paper, would insert it, thus disseminating information over a far wider circle of students than would otherwise be the case.

The withdrawal of the concession has not affected us, and we give it merely as an example. The reason for its withdrawal was, we believe, really a personal one, and thus students at large suffer through an attack of bile. When the influence of certain men was paramount at the Society of Telegraph Engineers few facilities were given to us for the publication of the papers read. The remedy we would propose would be for societies to adopt the plan given up by the Royal Society, viz., allow the printers to supply to editors of technical journals proofs of the papers read upon the day of reading or the next day. A better plan would perhaps be that the societies undertake to send out such proofs to a few papers. The number of first and second rate technical periodicals is very limited, and hence the cost would be very small. We are prepared to be misunderstood in our advocacy of such a plan, but we must, nevertheless, say that our advocacy depends upon no thought of personal benefit. Our columns are a sufficient proof that there are few papers we desire that we cannot obtain; in fact, our friends and contributors are, if possible, too generous, and it is to their ability and energy that the success we have attained is due. We write for those who have not the same facilities that we have—for others than electrical students. The publication of the papers in the technical journals of the day would benefit one race of students only. Nor do we know of any method that would apply to successive generations of students except the book form. But we must to our history.

Electrical Railways.—We turn to this subject first because, so far as we know, the application of electricity to railways during the past year has been the first application in this country of the kind to anything more substantial than a toy railway. Two railways have been constructed, (1) at Brighton, (2) at Portrush. The line at Brighton is due to the indefatigable energy and enterprise of Mr Volk. It runs for about a quarter of a mile along the sea front, from the Aquarium. The motor is a two horse-power Otto gas engine, and was first used to drive a small Siemens $D_5$ dynamo, which was afterwards replaced by a Weston dynamo. The motor and dynamo are placed in an arch, previously used as a boathouse, under the roadway. The success of this experimental line has been so great that it is to be extended. The extension contemplated will ultimately reach along the sea wall, through a tunnel, and on to the Downs, and the gauge is to be widened. The immediate extension will be to the Free Pier. The cost of construction of such a line is very small, while its convenience and attraction in a place like Brighton is very great. We shall be surprised if similar lines are not constructed this year at several sea-side resorts. Deal and Eastbourne might take a lesson from their neighbour. The line at Portrush, in the North of Ireland, is of greater pretensions. It is between six and seven miles in length, with a gauge of three feet, and cost some £45,000. The engineer is Mr. W. A. Traill, assisted by Mr. E. B. Price, and the electrical portion of the work was carried out under the supervision of the late Sir W. Siemens. Besides these lines in actual operation, Professor Fleeming Jenkin is busily perfecting a system to utilise electricity for the transmission of goods, a system to which he has given the name of "Telpherage." Professor Jenkin's scheme has been so recently noticed (*vide* Vol. XI., page 589), that we shall content ourselves with simply quoting one or two sentences to recall the idea. An experimental line has been constructed on the estate of Mr. Pryor, of Weston. It consists of a series of posts sixty feet apart, with two lines of rods supported by crossheads from the posts. These lines of rods form an up and down line. The train consists of seven buckets or skeps and a motor. The gearing used is the "nest gearing," described by Professor Jenkin at the Southport meeting of the British Association. The motor gives about $1\frac{1}{2}$ horse-power, when required. A current is sent into the motor from a stationary dynamo, and the mechanical energy developed by the motor moves the train. The value of such a system is supposed to be in its cheapness, freedom from accidents, and continuous working. By this we mean continuity of train service, more especially in connection with goods traffic. We have no data by means of which we can ascertain the probable value of such a system. Altogether, then, the utilisation of electricity for the transmission of power is in the embryo stage. The field is large and full of promise, and it remains for the future to give the value of that promise.

Secondary Batteries.—Passing now to another branch of our subject, that of Secondary Batteries, the year just past has been altogether unfortunate. The batteries that were so prominent and so full of promise twelve months since have

Digitized by Google

disappointed their best friends. The Faure-Sellon-Volckmar battery can hardly be said to be anything but a doubtful success. We wish we could speak otherwise, for as will be seen directly we believe the field for the use of such batteries is enormous. The defects of the battery mentioned are well known, and as the battery has been withdrawn pending the introduction of a modified or new form we must assume that the defects were insurmountable. Let us hope for better things of the modification promised. We most unhesitatingly state that in our opinion the secondary battery will prove of the greatest advantage in incandescent lighting; indeed, we are almost tempted to say that for successful work on a large scale such batteries must be used. The ordinary conception of what is wanted is we fancy altogether wrong. Practical and theoretical men have been led astray by the considerations put forward in the time when the world seemed to have lost all command of itself in everything concerning electricity. Inventors and investors have been driving at perfection, which they are as likely to attain as perpetual motion. Give us a battery that is fairly good, that will last without constant supervision for a reasonable time, and it will not be long before it is extensively used. It seems to us that the theoretically perfect battery is absolutely useless as a practical battery. Few batteries will be wanted for simple storage, fewer still to store for any length of time, but the great majority will be used as regulators; to give a constant E.M.F., supply a momentary loss, and perhaps to store sufficient energy for use in a moderate number of lamps before or after the engines are at work, or to store sufficient that smaller engines may be constantly run. We want batteries that are always being charged and discharged, never free, never empty. Woe to any battery as at present constructed when completely charged! The investigations of nine-tenths of workers during the past two or three years have been, we will not say worthless, but of far less value than most people imagine. It is not the battery that will give *the* best result in volt-amperes that will be used, but rather one that, as we have said, is *fairly* good all round; one giving a tolerably high E.M.F., not disintegrating under a long continued current, nor bulging to bursting when charged. We doubt if the battery to be used can be made of a metal or metals of different degrees of density with plates shaped like those of the ordinary Faure-Sellon-Volckmar type. Who is going to provide us with what is required? Is the Planté, the Elwell-Parker, the FitzGerald-Crompton, the Barnett, or any other satisfactory? Perhaps 1884 will decide this, for we understand preparations are made or being made to produce some of these batteries on an extensive scale.

Electric Lighting.—We now approach the burning question of the day. Last year was a year of promise unfulfilled. The promised harvest has not been gathered; indeed, the ripening seems to go backward instead of forward. At the beginning of 1883 everybody looked forward to provisional orders as all that they could desire. The provisional orders have been granted, but where are the signs of activity? True it is that at the recent meeting of the Swan Company—one of the most unsatisfactory meetings of the year—it was stated that the Victoria installation was sufficiently advanced to see the beginning of the end, and that ere long it would be at work. We feel bound to explain our use of the term usatisfactory used just now. The company was said to be "playing a waiting game," and we think that a waiting game may be played too often and too long. There was a good deal of talk, too, about the value of patents and their validity. Such questions if raised are liable to comment, and our impression is that the less said about them the better. The Edison and Swan Companies have shown their wisdom during the year in shaking hands and turning away from the law; we think they would be well advised to trouble little about threatening infringement. Some very curious statements have been published and discussed over forty years ago that, if arrayed in a law court, would produce a most decided sensation—at least we think so. To return to the subject of provisional orders. Were not many if not most of these orders obtained merely as baits to speculators, and was there ever any intention to carry out the orders? We believe in the *bonâ fides* of the Swan, the Edison, and one or two other companies as regards the orders. They have got what they wanted, and they mean to carry out the work. In other cases the companies that have obtained orders have no money for the work, nor can they in the depressed state of the market get money to carry out the work. They wanted to run before they could crawl; the result would most likely prove incapacity either to crawl or run. The provisional orders, then, have not hitherto opened out that mine of work and wealth that was expected of them. The progress of the year has been in other directions; but before detailing the work of individual firms, we may ask the question whether any decided advance has been made towards perfecting the apparatus employed? So far as incandescent lamps are concerned, the same makes are most prominent now as were most prominent a year ago. There has appeared no competitor to overshadow these makes, although keener competition is promised. The Swan and Edison lamps are far and away before any others. The Maxim and the Woodhouse-Rawson are used to a more limited extent. The Cruto is said to have been wonderfully improved during the time which has elapsed since the Munich Exhibition, while at Vienna the Bernstein met with a very considerable amount of favour. We have at various times commented upon these lamps, so that further remarks are uncalled for here; in fact, we have nothing to add to what has been said already. We assume that improvements in the manufacture are being constantly made in the case of all these lamps. If electric lighting is to be at all successful, there is room for all those mentioned, and more. Once more may be stated the belief in the ultimate approximation of such lamps to the same resistance and the same radiating surface, so that any lamp may be replaced by one bought at the nearest shop without difficulty. Lamps will be sold much as gas burners are now. Mention has already been made as to the position of batteries. The world has certainly not been startled in that direction by progress. The same may be said of the leads; but this brings us to the dynamo. Improvements in dynamos have been made of great value and importance. Hopkinson has greatly improved the Edison machine (smaller sizes), Crompton has done as much or more for the Bürgin, the Brush Company has brought out the "Victoria," a modification by Mordey of the Schuckert, improvements have been made in the Elphinstone-Vincent, whilst no doubt scores of machines have been invented, and mostly patented which will serve no other purpose than to amuse the inventors, increase the funds of the Patent Office, and distract editors. Of a truth the three months old student of electricity is a power in these days. He invents and patents. That remark is not correct. He patents and does not invent, for the simple reason—he cannot. Invention is not impossible in these days, but, as a rule, the knowledge required to invent a piece of electrical apparatus is rather more than is possessed by the majority of those who trouble the Patent Office.

The improvements we have named are not final, nor shall

Digitized by Google

we be surprised to hear shortly of other improvements from the same quarters. That a good deal of experimental work has been done is no secret, nor is the fact that results of a satisfactory character have been obtained.

Just as we meet the old names of incandescent lamps and machines, so we meet the old names of arc lamps. A good deal of difference of opinion is to be found concerning the future of arc lamps. On one hand we have those who think the field for arc lamps is almost or quite as wide as that for incandescent lamps, while on the other hand we have those who think incandescent lamps will almost wholly occupy the field of lighting. No new arc lamp has yet been brought forward to compete with the well-known types. Of course these latter are constantly being modified. Crompton, Brockie, Siemens, Brush, hold their own, while Lever, Bowman, and others hope the future will smile upon them, and that their inventions will come to the front. Whatever be the future of arc and of incandescent lighting, it is certain that, as we have said before, if success is but moderate, there is plenty of room for each and all of the better types of lamps.

The weak point at present existing is the want of confidence which is shown to exist on every side. Nor will the confidence of the general public be increased by such exhibitions of incompetency, as have recently been shown in one or two very large installations. Without particularising, it may be said that failure is courted when a large installation is carried out by a host of sub-contractors, without adequate supervision. One contractor does the wiring, another provides the fittings, a third provides the lamps, a fourth the dynamos, a fifth the engines, and so on, the contractor for the whole standing aloof, taking it for granted that everything will be right—looking, however, closely after the "finance." Incompetency and its adjunct, bad workmanship, will prove almost as great a curse to electric lighting as wild speculation.

Speculation.—It is very singular that the weak-kneed companies and firms are never found advertising their wares in a technical journal. Their only hope is to catch the ignorant, and hence they carefully avoid coming into contact with consulting engineers of repute; and we of course assume that "consulting engineers of repute" do read the technical papers, and have some knowledge of the progress that is therein recorded. So far as we can see there is no other way of instituting comparisons between machines and apparatus except the careful study of the papers.

A reference to our issue of January 6, 1883, pp. 101-2, will show that upwards of fifty companies connected with electrical matters were floated in 1882. The past year's record of companies floated dwindles to an insignificant figure, viz., three. These were:—

| Name of Company. | Capital Authorised. | Capital Offered. | Amount of Share | Deposit. | Total Deposit. |
|---|---|---|---|---|---|
| 1. Charing Cross and Waterloo Electric Railway | £ 100,000 | £ 100,000 | £ s. d. 10 0 0 | £ s. d. 2 0 0 | £ 20,000 |
| 2. Long Distance Telephone | 600,000 | 600,000 | 5 0 0 | 2 10 0 | 300,000 |
| 3. Simplex Electric Light and Plant | 40,000 | 30,000 | 5 0 0 | 2 0 0 | 12,000 |

One of these may survive; the others—well, it is not wise to attempt to prophesy. Of the numerous companies promoted in 1882, many were children. The promoters then proclaimed in glowing and eloquent terms of the advantages of numerous branches. The same men are now expatiating on the advantages of concentration, and calling the chickens to roost once more under a parent's wing.

Engines.—One of the most important questions that an electric light engineer has to consider is that of engines. Shall they be fast speed, coupled direct to the dynamo; shall they be slow speed, and used with counter-shafting? These and other questions have to be decided when preparing the specification for an installation. The remarks we hear about gas engines are most contradictory. For example, an eminent engineer put down a gas engine as motor in an installation, but the gas engine had to be replaced because it played all manner of pranks, stopping when it should have shown at its best, working at its best when nothing particular depended upon its action. The fault was traced to a nut. The use of the nut in the particular position saved perhaps sixpence, perhaps twopence, to the makers; the use of the nut lost the electrical world a few orders, and conduced to an extended use of the vernacular, as well as diminishing the confidence of those who went to see the show. We do not care to specialise failures, but may be allowed to mention that Mr. Volk speaks very highly of the Otto gas engines he has tried at Brighton. Mr. Swan, too, uses two small Otto engines at his house, and we believe is quite satisfied with their work. The same contradictory accounts are given concerning steam engines, which, perhaps, is nothing but what one should expect. Hitherto builders of engines have practically sold engines constructed on the old lines for special work. We have maintained, and we do maintain, that an engine designed for general work can hardly be successful when used for special work. The mere putting a sensitive governor upon an engine does not constitute it a good electric light engine. We believe some firms are beginning to see this, and are paying more attention to the requirements, and, if they have not already done so, are designing engines to satisfy the special conditions. The most prominent firm of engine builders during 1883 has been that of Davey, Paxman, and Co., of Colchester, whose engines were at work at the Fisheries Exhibition. When it is remembered that this firm undertook at a very short notice to supply engine-power to a given extent—and when it is also remembered that the actual power required was far above that estimated—the firm must be congratulated on coming out of the ordeal as well as it did. We do not remember that any other firm has done special work during the year, but the engines of Marshall, of Ransomes, of Hindley, and of Armington sustain their great reputation.

The work of individual firms may now be mentioned. It is not expected that the details are complete, nor can we mention every installation; indeed, the holidays have come rather inopportunely for us, and much promised information is not yet to hand. The order in which the various companies or firms are mentioned is perfectly accidental, and due to no consideration of superiority or inferiority.

Messrs. Edmundson and Co., of 19, Great George-street, Westminster, have for many years made a speciality of lighting country mansions. Foreseeing the capabilities of the incandescent light, they obtained the wholesale agency for the Swan lamp, and have carried out a number of private installations. Amongst others we may mention the lighting of Didlington Hall, Brandon, with 150 Swan lamps. A twelve horse-power gas engine is used as the motor. Another mansion at Ivybridge has been similarly lighted. Warter Priory, near Hull, is lighted with 180 lamps, and a Marshall steam engine is used. Avenue House, Finchley, is

Digitized by Google

lighted by 110 lamps, another mansion at Champion Hill with 180 lamps. Gleadalough House, county Wicklow, has 40 lamps, and here a turbine is used. Messrs. Edmundson tell us that in all their installations the lights are worked direct from the dynamo without the intervention of accumulators, for which little need has been found, "although should a reliable form of accumulator be discovered, requiring only a moderate amount of attention, these will no doubt be valuable additions, enabling the few lights required in the day time and late at night to be worked when engines are not running." This firm has given a good deal of attention to the fittings required in electric lighting.

Messrs. R. E. Crompton and Co. is a firm which stands pre-eminent in the introduction of the electric light. If the history of the electric light work of the past few years is ever written it will be seen that the success attained is due in great part to the untiring energy of the members of this firm, coupled with their ability. Difficulties have arisen only to be overcome. While other companies and firms have been bewailing the want of work, the lack of confidence, the horrible depression, this firm has been busily engaged in more than doubling the size of its works at Chelmsford, and executing the orders received. During the past year they have so modified the Bürgin machine as greatly to increase its output. They have introduced the compound winding, which has given us machines that practically regulate themselves. The compound winding is now to be found in almost all the well-known types of machines, but there is little doubt the work of this firm first brought it into popularity. Messrs. Kapp and Crompton invented the measuring instruments described by us in our issue of October 13, 1883. The further use of these instruments is said to have proved their value, and we believe they are now being used as standard instruments. The original form of Crompton arc lamp has been greatly modified, and in the arc lamp invented by Messrs. Crompton and Crabb we have a great advance upon the old pattern. Another invention which, as yet, we have not described, but which is said to work well, is an electric governor, the joint production of Messrs. Willans, Hartnell, and Crompton. We have always hesitated about describing things from patent specifications—although some of our contemporaries seem to prefer such descriptions—or from hearsay evidence. We prefer waiting till we have seen this governor, or obtained trustworthy figures before saying more. A gentleman of our acquaintance who has had great experience has always insisted that arc lighting had a much greater field than was generally allowed, and no doubt this feeling is shared by others. It may interest them to know that in the early autumn a suddenly-increased demand set up for arc lamps of the Crompton-Crabb type, and that this demand has continued so as to tax all the energies of the works to supply the orders; in fact, a large part of the works have run continuously day and night to meet the demand, orders are still on hand, and providing work for some months to come.

One of the Telpher locomotives has been made for the Telpherage Company by this firm. We must bring this notice of Messrs. Crompton's work to a close by mentioning a few installations carried out by them or their agents. Such are installations for the London and South-Western Railway Company, Earle's Shipbuilding Company, the town of Turni, Italy; Royal Courts of Justice Chambers Company, Forth Bridge Works, Leeds Municipality, United Swan and Edison Companies' Victoria installation, additional contract for the Royal Courts of Justice. They have also supplied the machinery to Messrs. Norman, for Pullar's Dye Works, Grangemouth Docks, &c. To Wilson Hartnell, agent for Leeds, they have supplied the apparatus for Thwaites and Co., Messrs. Pollett and Wigzell, Swan and Hunter, Barran and Co., &c.; to Mr. J. C. Howell, Llanelly, machinery for various tin plate works in South Wales, as well as the Ocean Collieries. Many of the electric light companies have also given orders to the firm, and thus the record extends.

The Paris Edison Company.—It will be no surprise to many of our readers to see the success which has attended the work of this company. Mr. Bachelor and those with him have tried hard to deserve success. Some of his colleagues—Mr. Jehl, for instance—are also well known to many of us, and known to have their hearts in the work. It may perhaps be more interesting to describe the work of this company in a tabular form, so that the progress of the Edison system in various Continental countries may be seen at a glance. It must, however, be remembered that there is also a Berlin company, and that a number of installations have been carried out from England. Two hundred and fifteen installations, including three central stations, with over thirty thousand lamps, is a good beginning, and we hope progress will continue in geometrical progression. The tables as kindly supplied to us are sufficiently clear without translation, so we give the originals:—

Résumé.—Il a été fait dans les différents pays d'Europe depuis le 17 Février, 1882, jusqu'au 31 Août (à l'étranger) respectivement jusqu'au 12 Novembre (en France), 215 installations permanentes (dont 3 stations centrales), employant au total 31,339 lampes.

THE AUSTRALASIAN ELECTRIC LIGHT COMPANY.—When the electric light was deemed practicable it was suggested that important openings for its use would be found in the Colonies, and various companies were formed for working these fields. Among others the company now mentioned was formed, and has succeeded in doing a steady business. In *Melbourne* the corporation have had some street lighting carried out, while the Spencer-street Railway Station and the Houses of Parliament have been lighted for the Victorian Government. The works of the Meat Freezing Company and the Bourke-street Arcade have also been lighted. Some of this lighting is with arc, some with incandescent, lamps. At *Sydney* the Theatre Royal, the Circular Quay and Docks, the Government Printing Office, and the Sydney Arcade have been lighted. In *Queensland* sugar factories and railway stations have been lighted, the latter at Brisbane. Nor has the work of the company been confined to Australia, for in *Figi* several sugar planters have adopted arc lights. In *Tasmania* the exhibition was lighted by electricity while open. In *New Zealand* installations have been made at Lyttelton Harbour, and the *Otago Times* office. The company is rather cosmopolitan in its use of apparatus, for it has sent out plant of the types following:—Brush arc dynamos, Ferranti incandescent machines, Hopkinson, Brush-Schuckert, and Victoria machines; Fyfe-Main, Brush, Pilsen and Gulcher arc lamps; Lane-Fox and Swan incandescent lamps; Elwell-Parker-Planté storage batteries. It will be seen from the foregoing condensed details that the work has been very varied. In addition to the permanent installations specified, a considerable number of temporary installations have been put up, which has greatly familiarised the colonies with the electric light. The type of plant and machinery in use shows the universality of the company. It is not confined to any particular patent, but is free to use the best of everything which is to be found in the market. Three of the Governments are already customers of the company, and the consulting electrical engineer of the Victorian Government in particular is a staunch adherent. The company are also using many improved fittings designed by their London engineer.

THE MAXIM-WESTON COMPANY.—This company has referred us to the Christmas number of *The City* for information. Our rule is to have direct and trustworthy information, and as the company has seen fit to refer us to another publication, we are fain to give the hint to our readers.

M. VOLK (Brighton) has during the year carried out an installation at the Pavilion, Brighton, with Swan lamps and a Siemens machine.

THE WOLVERHAMPTON ELECTRIC, &C., COMPANY, manufacture the Elwell-Parker storage battery. This battery is a modification of Planté's, the plates being rendered porous by a nitric acid process. We are informed that a very larger business is being done both at home and for export. The company also construct dynamos and engines, and is in this department also busy.

ELECTRICAL POWER STORAGE COMPANY.—The work of this company may be divided into two classes, namely, (1) preparation of accumulators for electric lighting, and (2) for motive power. It was only at the beginning of the year that the accumulators were put to public use, and experience, while affording evidence of the value of accumulators for domestic lighting, if not their absolute necessity for this purpose, has shown many points in which improvements have been made and further improvements are anticipated. Electric lighting by means of accumulators has been introduced into hotels, such as the Grand, and Army and Navy, London, Grand Hotel and Eberle's Restaurant, Liverpool, &c., and in theatres at the Gaiety and Mr. Bruce's new theatre, the Prince's. In large business offices there have been installations at the Peninsular and Oriental Company's offices, Messrs. F. Green and Co. (the Orient Steam Shipping Company), while probably the most important installation in London, if not for size certainly from its exceptional position, is that in the Bank of England, with which this company has been entrusted after a most exhaustive inquiry by the governor and some of the directors. It is anticipated that the alterations at the Bank will be completed early this year, so that the working of the installation may then commence. Installations at country mansions, private residences, &c., have been numerous. Messrs. R. E. Crompton and Co. included a set of accumulators in the installation at Lord Randolph Churchill's, whilst Sir David Salomons, Mr. Henry Hucks Gibbs, Mr. Alexander Henderson, and other gentlemen have had the accumulators fitted up.

As regards motive power, we recorded in our columns the successful application of stored electricity in the launch built by Messrs. Yarrow and Co. for the Vienna Electrical Exhibition. The experiments undertaken in England as regards tramcar propulsion were continued in Paris by the French Electrical Power Storage Company, and the speed attained, the distances run, and the complete control exercised over the car showed the practicability of the system.

On two branches where stored electricity is destined to obtain an extensive employment the accumulator has been

Digitized by Google

working with perfect success. We mean railway train lighting and railway signal working. The preliminary trials have been made by competent railway officials, and it is stated in both cases that the results have been most successful, and early in the year it is hoped to see railway trains lit in a manner leaving nothing to be desired. In the box type of accumulators to be supplied in 1884 many improvements will be found facilitating their working in unskilled hands, and the new type now being investigated and experimented upon by the company will enlarge the scope of usefulness and adaptability in a marked degree.

(TO BE CONTINUED.)

## CORRESPONDENCE.

### HEAT, LIGHT, AND POWER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I venture to offer the following suggestions for discussion in your columns:—Undoubtedly the supply of light, heat, power, water, &c., to a town should be undertaken by the town itself, whose interest it would be to do it well and cheaply, charging just enough to cover expenses, or devoting any profits to the improvement of the town, rather than by companies from without, who should make it their business to carry out the engineering and manufacturing works only, and not to raise capital for local purposes. The distribution of the first three of the above-named commodities might, with advantage, be included under one system. Coal, which might be of almost any description or quality, instead of being distilled, should be wholly converted into carbonic oxide, to be distributed for heating purposes, and also to be utilised for working gas engines to drive dynamos. The great hindrance to the distribution of electricity on a large scale now appears to be the difficulty and cost of providing an efficient and durable system of conductors. For this purpose I would use bare wire or rod supported by insulators fixed inside the gas mains, well insulated branch leads being taken from this into the houses through the gas supply pipes. If the E.M.F. were sufficiently low the return wires might be connected to the pipes, thus forming a good earth return. There might also be wires of smaller section attached to separate insulators inside the mains for carrying currents to light the streets by arc lamps in series. Consumers would have their choice of two sources of power—electric motors, taking their current from the same leads as the lamps, or gas motors, using the heating gas. The advantages of the system are as follow:—Amalgamation of works, both for production and distribution; utilisation of existing gasworks and mains; economy of production of electricity, small gas engines using this gas being as economical as large steam engines, and the system of a series of small engines driving, through a single countershaft, a series of dynamos being more reliable than that of large engines, each driving one or more dynamos, or at least requiring less idle plant, and allowing of gradual extension to meet increased demand. Also, while there are only one or two gasworks to a town, there might be many electric generating stations, a few gas engines and dynamos requiring little space, and no facilities for bringing coal or disposing of ashes, and causing no nuisance. In some cases large consumers might prefer to generate their own electricity. This arrangement would be conducive to economy of conductors and uniformity of potential. Lastly, the economy, efficiency, and durability of conductors. This is the point on which I should like the opinion of electric and gas engineers—would the copper be destroyed by the gas, and would the insulation be lowered by condensation of solid or liquid matter from the gas on the insulators at too rapid a rate for keeping them clear? Of course, the gas for heating need not be purified, unless for the sake of residual products; but, on the other hand, it would be composed mainly of more permanent gases than the hydrocarbons, and it might be found practicable to deprive it of any corrosive elements, such as sulphur, without unduly increasing the cost.

The conversion of the existing gas plant might be quite gradual. For example, the conductors for street lighting only might first be inserted in a part of the mains that could best be opened for the purpose, and a trial made with portable engines consuming the gas coke. Next a duplicate system of mains—they would afterwards be required for the increased consumption of gas—might be gradually extended from the gasworks, fitted with the electric conductors, and a few of the new gas producers, an extra gasometer, and a few gas engines and dynamos being set up. The heating gas and electric current could be supplied through these new mains without interfering with the supply of the old lighting gas, and these being gradually spread over the town parallel with the old mains, the conversion of the gasworks keeping pace with the changed requirements of customers, might in the end be connected with them at intervals by valves and both sets be given over to the supply of the new gas and electricity. Manholes being placed at intervals so as to be got at without disturbing the streets, and valves between them (the conductors being taken out round the valves through testing boxes), any section could be cut off from all others and from the parallel main, and entered for cleaning, repairing, or altering connections without interfering with the supply.—Yours, &c.,

ARTHUR J. HILLS.

Chilcombe Lodge, Winchester, Dec. 28.

### SCIENCE AND ART.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the admirable article in your last issue on the above subject you appear to be of the same opinion as Sir Charles Dilke in thinking that "science can take care of itself."

So long as human nature is constituted as it is such a phrase must remain a truism, because science *and its applications* have a remedy which is almost infallible by appealing to the selfishness of mankind in providing and increasing the wealth and comforts of the world. To consider it, therefore, as of secondary importance to art would be inconsistent with facts, and the art advocates who propose it are simply cutting the ground from under their feet. Would it be reasonable to look upon the bridge at Blackfriars as of secondary importance to the statuary by which it is soon to be adorned? The bridge itself is of immense utility, and the scientific knowledge which enabled it to be constructed will be the means of affording a valuable commission to the sculptor. Had there been no bridge, however, there would have been no statuary; so that in this case the scientist has provided a field for the artist.

Art, however nurtured, cannot be made to create wealth except in a very indirect way; in fact, it cannot exist without wealth. It is true that art has a refining influence on those who view it, and is the means of keeping people in good temper, thereby increasing their chance of longevity, and so enabling them, with the aid of science *and its applications*, to still more increase the wealth and comforts of the world, and to provide more commissions for artists.

No amount of art culture could have facilitated the discovery of the circulation of the blood, or else we might have reasonably expected the Greeks to have anticipated the immortal Harvey; neither could it have afforded much assistance to Newton, Watt, Faraday, and others otherwise than as a recreation.

Science exists even in art itself, inasmuch as the very basis of art is construction; and you cannot construct without science, either knowingly or unknowingly.

Apart from utility, science must always be a more ennobling study than art, because art is the work of man, while the study of science enables man to fathom and grasp the apparent mysteries of the works of an infinitely greater than man.—Yours, &c.,

VOX.

December 29, 1883.

[Neither the writer of the article in question nor the per-

Digitized by Google

sons to whom it referred raised the question of the relative "wealth increasing" powers of science as compared with art. The simple question was, Which of them stood most in need of being tenderly cared for in these days?—Ed. *E.*]

## WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

Sir: It is over twenty years since I wrote a letter to *The Electrician*, giving my opinion that the effects called magnetism were caused by the rapid rotary motion of the current around the wire. Desmond FitzGerald was editor then, and he inserted my letter, at the same time saying that the general opinion was magnetism was a separate force, always existing with and acting at right angles to it.

Now, one of the questions in your journal is—Is electricity a fluid? I am on the side of those that think it is, and that the dynamo machines are simply pumps to pump it forward. Only I think that the present dynamos are constructed on wrong principles; that they act by induction in place of reaction. This necessitates the use of that foolish piece of mechanism called the contact breaker or commutator. The machines of the future will have no contact breaker, and yet produce a continuous current. I have doubts myself if iron is required at all. It may be as a generator, but the motors of the future will be constructed without a particle of iron in them. No doubt my opinion will be laughed at, but if I were rich instead of poor I would soon have the laugh on my side. Wishing prosperity to the trinity of heat, light, and electricity, yours, &c., B. R. Mills.

16, Warwick-street.

## RECKENZAUN'S BRAKE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: If your correspondent, M. Villard, will take the trouble to read the text of my article, to which Figs. 6 and 7 are illustrations, he will find that the apparatus in question is called Raffard's brake. But, since the particular form of Raffard brake which I illustrated was designed, made, and used by Mr. Reckenzaun, and, moreover, differs considerably from the design published by M. Raffard in the *Bulletin*, No. 212, I have called the illustrations Reckenzaun's brake instead of giving it the longer title, "Raffard brake, designed by Reckenzaun." In the same way we speak of a Siemens bridge, when we mean a Wheatstone resistance bridge, made by Siemens. The custom of writing short titles under the illustrations which will catch the eye in looking through your pages is a very convenient one for future reference. Of course, it can only be done on the supposition that the intelligent reader will also pay some attention to the text.—Yours, &c.,

Gisbert Kapp.

Chelmsford, December 31, 1883.

## PRIMARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Would any of your readers give me some information regarding the latest forms of primary batteries suitable for large currents, and whether there are any books from which I could obtain any information on this subject?—Yours, &c., H. J. W.

January 2, 1884.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I am grateful to "R. H. M. B." for his able description of the conditions of a successful dynamo.

I cannot, however, quite understand paragraph 8 of his letter. My machine has but one field magnet, its two legs being coupled in series. Does it, then, require 10,000, 5,000, or 2,500 ampere turns to saturate it? This doubt clouds my understanding the first two equations. And how is the third equation arrived at? As I have since writing rewound the F.M. to better advantage, I subjoin the revised data (reckoning the two legs of the F.M. together).

Main circuit on F.M. ·5 ohm 100 turns B.W.G. 16.
Shunt circuit on F.M. 9 ohms 600 turns B.W.G. 22.
Armature (as before) ·4 ohm 84 turns B.W.G. 16.
Section of web of armature 19 sq. c.m.

I should like to submit to "R. H. M. B's." criticism a new form of armature if he would not mind the trouble.—Yours, &c., R. W. Oldham.

Wellow, Romsey, Jan. 2, 1884.

## SMALL DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I should consider it a great favour if you would kindly inform me the gauges and quantity of wire required for the armature and field magnet of my dynamo. The field magnet is of an inverted U shape, the height from bed plate to top of curve 8in., the breadth of each leg 4½in., the thickness ⅜in., the space between legs 1¾in. It is made of cast iron, having pole pieces cast at each extremity, and bored out to take small Siemens armature, with $\frac{1}{64}$in. clearance. The casting contains about 45 cubic inches of metal. The armature is 1½in. diameter, and H shape in section. The grooves are 1in. wide, and deep enough to leave ¼in. of metal, on which the wire is to be wrapped; the length is 5⅓in. between caps. The object of the machine is to supply four incandescent lamps, about 5 candle-power each.

An answer would greatly oblige, as I am quite at a standstill about the particulars of the wire.—Yours, &c.,

E.T.N.

## STANDARD OF RESISTANCE FOR COPPER WIRE.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Will you or one of your readers kindly tell me what you consider the best standard of resistance for copper wire, and its specific gravity?—Yours, &c., H. G. C.

## PATENTS FOR DISTRIBUTION OF ELECTRICITY.

BY C. A. STEPHENSON.

*Secondary Batteries.*

As soon as any attempt was made to introduce secondary batteries into a system of distribution it was found that they acted to a great extent as regulators. In due course I shall deal with them under that head; for the present I shall merely treat of the broad principles of the several methods of introducing them into circuits.

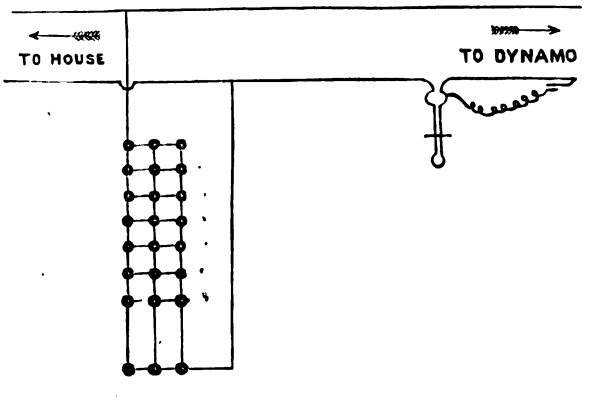

Fig. 9.—Arrangement of Circuits for Lighting Sir W. Thomson's House

In *The Electrician* of 29th April, 1882, p. 389, there is a description of an installation at Sir William Thomson's house in Glasgow. It will be seen from the drawing (Fig. 9) that the batteries are here introduced in a shunt circuit.

In November, 1882, Mr. Lane-Fox issued a pamphlet describing an installation at the Théâtre des Variétés in Paris, and claiming the system as being the same as was

Digitized by Google

patented by him in October, 1878. Fig. 10 is the plan issued with the pamphlet. P is the generating station, M mains or conductors, A secondary batteries, L *o* lamps, R *n* returns, $X_1$ meters.

It is not clear how the returns are led back to a generator, but the pamphlet states that this can be "conveniently and safely effected by means of a gas or water pipe," otherwise the plan fully explains itself.

*Induced Currents.*

The system of distributing electricity by means of branches fed from secondary currents of a primary main has never yet been tried on an extended scale. It would therefore, perhaps, be premature to judge of its merits; but one very significant fact cannot be overlooked. The first two patentees abandoned the idea at so early a stage that neither of them thought it worth while to proceed beyond a preliminary specification. The first in the field was Sir Charles Bright. In patent No. 4,212 of 1878 he describes a system by which the primary coil of each induction apparatus is in the circuit of a metallic main conductor; the ends of the secondary coil of the induction apparatus form a branch. The current is regulated by altering the resistance in the primary coils. The next patent was that of M. Auguste de Meritens—No. 5,257 of 1878. In this system the mains are fed with alternating currents. At points where branches are required

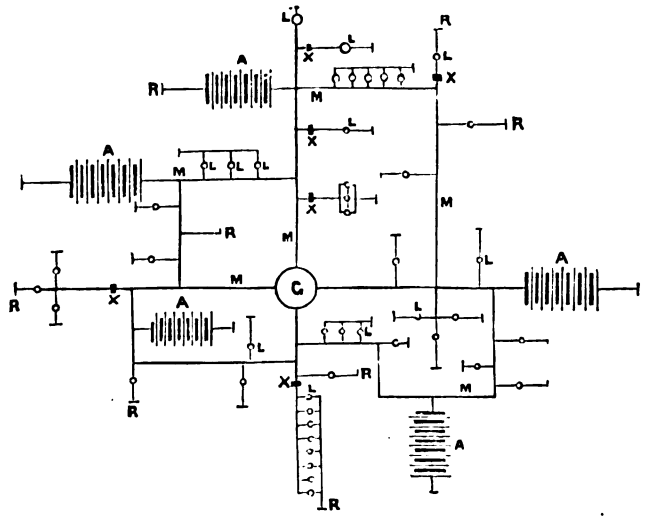

Fig 10.

the coils of electro-magnets are introduced into the mains. As the current is alternating, it follows that the electro-magnets are continually reversing polarity. Opposite and in proximity to the poles of these electro-magnets other electro-magnets are placed, the ends of the coils of which second electro-magnets form the branches. As the cores of the first electro-magnets are continually having their polarity reversed, they induce a similar action in the cores of the second electro-magnets, which again induce alternating currents in their own coils, the ends of which coils form the branches. Thus the main current from an alternating current machine passes through the coils of an electro-magnet, producing in it by induction a constant reversal of polarity. The second process is that the first electro-magnet produces a similar but reverse polarity in a second electro-magnet, and the third process is that the second electro-magnet produces an alternating current in its own coil. Ingenious as this process is, M. de Meritens did not consider it worth while completing his patent. The loss of transferring electricity by such means from mains to branches must be very great, and there does not appear to be any corresponding gain.

A very similar process of distribution was patented by Messrs. Gaulard and Gibbs in 1882 (No. 4,362). The induction apparatus differs in detail from M. de Meritens'. The first claim is for "The employment of an alternating current of high tension for the generation on an unlimited number of secondary generators of induced currents individually utilised either for the production of light or motive power." There is nothing in this claim that has not already been described in M. de Meritens' patent, except, perhaps, that a "high tension" current is used.

There remains now but one more process to describe, namely, distribution by

*Rapid Makes and Breaks.*

The idea is that if the makes and breaks are sufficiently rapid the effect as regards the lamps would not be noticed, whilst there would be a great saving of electricity. These anticipations I need scarcely say have not been realised. The idea originated with Mr. John Munro, who took out a provisional specification, No. 4,016, in 1878. He did not proceed with the patent. He was shortly afterwards followed in the same idea by Mr. E. J. C. Welsh, whose patent, 4,114, of 1878, is void, and later, in 1879, Mr. A. L. Cooke took out a provisional specification, No. 1,012, which was also abandoned.

This concludes the main principles which have been brought forward for the distribution of electricity. In matters of detail many and various improvements have been made, and I shall deal with the patents for these under the head of "Regulation."

---

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 166).

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

### HISTORY IN RELATION TO TELEGRAPHY.

There was, however, still wanting another discovery to bring the galvanometer to its present perfection, and this want was soon supplied. In deflecting a magnetic needle the current acts against the directive force of terrestrial magnetism; hence it is clear that if this force could be neutralised the deflection would be greater; in other words, a galvanometer, in which the needle is freed from the controlling action of the earth's magnetism, would be more sensitive than the same galvanometer whose needle was not so freed. Ampère suspended a single needle so that the earth's magnetism acted perpendicularly to it, and had, therefore, no directive force upon it; and he found that it set accurately in a direction perpendicular to the current.

This led him to the invention of the double, or *astatic*, needles, which he thus describes in his memoir of 1821 (*Annales de Chimie et de Physique*, Vol. XVIII., p. 320):—

"When a magnetic needle is withdrawn from the directive action of the earth, it sets itself, by the action of a voltaic conductor, in a direction which makes a right angle with the direction of the conductor, and has its south pole to the left of the current against which it is placed; so that if M. Œrsted, in the the experiments which he published in 1820, only obtained deviations of the needle which were less than a right angle, on placing it above or below a conducting wire parallel to its direction, it was solely because the needle which he subjected to the action of the current was not withdrawn from that of the earth, and took consequently an intermediate position between the directions which the two forces tended to give it. There are several means of withdrawing a magnetic needle from the earth's action. A very simple means consists in attaching to a stout brass wire, which has its upper part curved and fitted with a steel point of suspension, two magnetic needles of equal strength, in such a manner that their poles are in opposite directions, so that the directive force of the earth upon one is destroyed by the action in the opposite direction which it exercises on the other. The needles are so arranged that the lower one is just below the conducting wires, and the upper one close above them. On sending a current through the convolutions the needles turn, until they take a direction at right angles with the conducting wire."†

Having oscillated a magnetised needle, freely suspended in a

* The author reserves all rights of translation.

† In Professor Cumming's paper "On the connection of Galvanism and Magnetism," read before the Cambridge Philosophical Society on April 2, 1821, he described a near approach to the Astatic needle. In order to neutralise the terrestrial magnetism he placed a small magnetised needle under the galvanometer needle. (*Trans. Cam. Phil. Soc.*, Vol. I., p. 279.) The credit of Ampère's discovery is usually attributed to Nobili. See Noad's "Manual of Electricity," London, 1859, p. 327; also Roget's "Electro-Magnetism," in Library of Useful Knowledge, London, 1832, p. 42.

Digitized by Google

circular copper cage, the bottom and sides of which were very near the needle, Arago, in 1824, noticed that the oscillations rapidly diminished in extent, and very quickly ceased, as if the medium in which they were being produced had become more and more resistant. The proximity of the copper, while thus checking the *amplitude* of the oscillations, was observed to have no effect on their *duration*, they being accomplished in exactly the same time as in free air. By making the needle oscillate at different distances above discs of different natures, Arago found that distance considerably diminished the effect; and that metals acted with more energy than wood, glass, &c.*

Arago now conceived the idea of trying whether the disc which possessed this remarkable property would not draw the needle with it if itself rotated. The experiment was tried and resulted in the discovery of a new class of phenomena to which Arago gave the name of *magnetism by rotation*. If we fix to a rotation apparatus, such as a table made for experiments on centrifugal force, a copper disc, about 12 inches diameter, and $\frac{1}{10}$ inch thick, and just above it suspend, by a silk fibre, a magnetic needle, in such a manner that its point of suspension is exactly above the centre of the disc (care being taken to interpose a screen of glass or paper, so that the agitation of the air resulting from the motion impressed upon the disc may have no effect upon the needle), and then put the disc in rotation, the needle is seen to deviate in the direction of this rotation, and to make with the magnetic meridian a greater or less angle according to the velocity with which the disc is revolved. If this movement be very rapid, the needle is deflected more and more, until finally it rotates with the disc.

The effect diminishes very rapidly with the distance of the needle from the disc; and is still further lessened by cutting slits in the latter in the direction of rays—a fact which, as our practical readers know, is of the highest importance in the construction of electro-magnets.

Whilst Arago was analysing the force that he had discovered, Babbage and Herschel, Barlow, Harris,† and others, undertook an investigation of the causes that may vary its intensity. Messrs. Babbage and Herschel repeated Arago's experiment by inverting it. They found that discs of copper, or other substances, when freely suspended over a rotating horse-shoe magnet, turned in the same direction as the magnet, with a movement at first slow, but which gradually increased in rapidity. The interposition of plates of glass and of non-magnetic metallic bodies in no degree affected the results; but it was not the same with plates of *iron*. The action was then greatly reduced, or even entirely annihilated.

These two philosophers confirmed the accuracy of Arago's observations on the influence of solutions of continuity, either partial or total, in the discs subjected to experiment. Thus, a light disc of copper, suspended at a given distance above a magnet, executed its (6) revolutions in 55″. When cut in eight places, in the direction of radii near the centre, it required 121″ to execute the same number; but, on the parts cut out being again soldered in with tin, the original effect was almost attained, the disc performing its revolutions in 57″. The same effects were obtained with other metals.

Sir W. Snow Harris, who made a great number of experiments on this subject, not only found great differences between bodies with regard to their power of drawing the needle after them when rotating, but also with regard to the property they possess of intercepting this action. He observed that iron, and magnetic substances generally, are not the only ones that are thus able to arrest the effect of magnetism by rotation. Plates of non-magnetic substances, such as copper, silver, zinc, will do the same, provided only they be sufficiently thick, as from three to five inches.

From a study of all these experiments Christie deduced the law that the force with which different substances draw along the magnetic needle in their rotatory movement is proportional to their conducting power for electricity. But a full explanation of these phenomena could not be given until after Faraday's discoveries in 1831, when it was seen that they were, one and all, the result of the electric currents induced in the disc by its rotation in the field of the magnet. In the case of those discs in which slits, or rays, were cut the free circulation of these currents was prevented, and consequently there was no effect on the needle.‡

* *Ann. de chim. et de Phys.* XXVII, 363. Seebeck, of Berlin, on repeating these experiments two years later, obtained analogous results. See *Pogg. Ann.* Vol. VII. We shall see in our next chapter the use that has been made of this fact in the telegraphs of Gauss and Weber, and Steinheil.

† For researches of the three first-named philosophers see *Philosophical Transactions*, for 1825; for those of Sir W. Snow Harris, see same for 1831.

(TO BE CONTINUED.)

## LONDON PLATINO-BRAZILIAN TELEGRAPH COMPANY (LIMITED).

An extraordinary general meeting of this Company was held at the offices, No. 66, Old Broad-street, E.C., on the 2nd inst., at which the following resolution for the purpose of enabling the Board to provide funds for paying off existing debentures of the Company, which fall due on the 1st day of March, 1884:—"That the Board be and hereby is authorised to create and issue debentures, mortgages, or obligations of the Company, secured upon all or any part of the undertaking, property, and revenues of the Company, for such amount as shall be sufficient to raise the funds for the purpose of paying off or exchange with the present 7 per cent. debentures falling due on the 1st March, 1884, charged on the property of the Company and its revenues; and that the Board may issue or dispose of the same for such sums of such nominal amount, at such prices, and bearing such interest, not exceeding 7 per cent. per annum, redeemable in such manner and generally upon such terms and conditions of issue or exchange as the Board shall think fit." The chair was taken by John Pender, Esq., M.P.

The SECRETARY (Mr. William Payton) having read the notice convening the meeting as above,

The CHAIRMAN said: Gentlemen, the object of this meeting is, as just stated, to take powers as to the reissue of the debentures which fall due on the 1st March next. These debentures were created by the original company, and, as you are aware, the Company is now an English company, and the debentures falling due will require to be issued by the new company. The amount of debentures is £100,000, and they bear interest at present at 7 per cent. We desire to-day by the resolution I shall propose to you to have the power to issue such an amount at such rates as the directors may find it possible to arrange, which I hope will be lower than 7 per cent. That, however, is a question which we require to deal with when we have this authority. He concluded by moving the resolution as above.

Mr. HOLLSCOMBE briefly seconded the motion.

Mr. ROBINSON KENDAL thought it would be well for the chairman to explain, as far as he could without committing the Company, upon what method or terms the directors were going to issue the debentures.

The CHAIRMAN: What we propose to do when we get this authority is to take steps to ascertain what we can place these debentures at. We must make an arrangement before these debentures fall due to get the money to pay them off when they mature. There are two ways of dealing with the matter. You might go to the shareholders and ask them to take the debentures, but if they failed to respond, then, to some extent, your own property would be depreciated. On the other hand, you might make an arrangement with some influential broker in London to take the £100,000 at some moderate discount which would give him a commission for the transaction. We should then offer the debentures to our shareholders at a price, all the applications, of course, being passed on to the broker who has taken the risk—who has taken them "firm," as the market call it. Beyond that we can make no statement till we come in contact with men who are prepared to look at the debentures as a matter of business. I think you will agree, Mr. Kendal, that that is as far as I can go now.

Mr. KENDAL observed that he had only wished to know if there was any scheme "cut and dried."

The CHAIRMAN: I have had a conversation with a leading house, asking them on what terms they are prepared to deal with the matter, so I have a rough idea of what is likely to be done. I may, however, have to inquire in other quarters, to see if the transaction can be done on cheaper terms. Replying to other questions, the Chairman added: My own idea is that we ought to place the debentures at 6 per cent., at some discount that will enable the broker to get his profit out of the issue. If the shareholders will come forward and take them, there is no necessity why you should pay a farthing in brokerage. We must, however find the money before the debentures fall due. There is a difficulty in the matter. The shareholders may take the issue, but they are not the holders of the present debentures, which are "to bearer." We therefore have a difficulty in ascertaining in whose hands the debentures are. We might ascertain the feeling of the shareholders as to taking the new issue by sending a circular to them; but you have to be careful. If the shareholders do not respond it would make it so much more difficult to make a bargain. Those who would take the £100,000 "firm" might naturally expect a good many of the shareholders to apply for the debentures, and the difference between what the shareholders would pay and what the parties would take them at would be the brokers' commission.

A SHAREHOLDER thought the new bonds would be readily taken at 6 per cent., and he therefore saw no reason to pay £2,000 or £3,000 for brokerage until the shareholders had refused to take them.

The CHAIRMAN: My own impression is that the bonds are remarkably good at 6 per cent. I have no doubt about that, because, though they are not a first charge on the Western and Brazilian property, they are "next door" to it.

Mr. W. FORD thought that after such an expression of opinion from the chairman they would most certainly float the bonds readily.

A SHAREHOLDER: Can we not invest our reserve fund in the debentures?

The CHAIRMAN: A reserve fund as a rule is kept for the purpose of maintaining your system in an efficient condition, and you cannot have it both ways. We find that bonds in telegraph companies do not circulate much—they generally get among those who hold them for investment. As one gentleman has said, the Telegraph Construction Company have just issued bonds at 6 per cent., but I think 6 per cent. an extraordinary rate for that company to pay. I was told that the issue was so entirely with their own shareholders that they wanted to give them what I would call a little New Year's gift. Every one of these bonds was taken up at once. There was no question about bonds of the Telegraph Construction Company, but our Company, as you know, was, as it were, plucked from the very fire. It was at one time as near ruin as it could possibly be. Now we are in a fairly satisfactory condition, but still not so satisfactory as I should like to see it. However, every improvement that takes place with the Western and Brazilian Company is an improvement for us, because our arrangement with the Western and Brazilian Company is a very decided advantage to us. We are what you would call preference shareholders.

Mr. KENDAL thought that what some of the shareholders desired was to

Digitized by Google

know definitely what the Board were going to do. He saw that there was some difficulty in communicating with the shareholders first, as their position might be prejudiced if they had afterwards to go to the outside public. He, however, suggested whether they could not make an arrangement with outside parties by which the latter might take the debentures if they were not accepted by the shareholders. He thought that the shareholders should have the first option, but he would like to know clearly what the policy of the directors was.

The CHAIRMAN: I have stated it clearly.

Mr. KENDAL: You have not stated whether you would ask the shareholders first.

The CHAIRMAN; That is true. That expression of opinion which has been made to-day by the shareholders is a point we have not considered: but what we have considered is this—that we would send out a notice to all the shareholders, offering these debentures at a price (having made an arrangement for their "firm" with a broker), and the price would simply be the difference between what they paid and the broker's commission. I presume, however, that the directors would approve of sending out a circular to the shareholders, and there is plenty of time to do it.

Mr. BAKER thought the shareholders would desire to have the option of taking the debentures, even if a circular were not sent round to them.

The CHAIRMAN: The shareholders will have the option of taking them.

Mr. BAKER: If so, why pay a commission on what the shareholders will take? I know a few gentlemen, for instance, who will take £10,000 of them, and why pay commission?

The CHAIRMAN: There is a principle, you know. I like to save money where it can be done, but you cannot go to a broker and place him in the position of "heads I win, tails you lose." A respectable broker would not be dealt with in that way. He would say, I must deal with the thing as a whole; I am prepared to deal with it for a moderate commission, and take the lot "firm."

Captain PAVY observed that he represented a very considerable number of the shares, and he wished the shareholders to take all the debentures they could. What he supposed the directors wished was to be put in a position to deal, and directly they were so placed they would be able to make a contract. There were several influential shareholders present, and if they would inform the directors what amount they would take it would help the Board. He himself proposed to take a certain amount for the institutions he represented, and if the shareholders would say how much they would take it might reduce the amount to such a small sum that the directors could deal with it. They must, however, first have the power of dealing with the matter which the resolution gave them.

The CHAIRMAN: Our idea has been to issue these debentures at 6 per cent., but we must first have authority to do it. We might have proposed companies, but as you know the Telegraph Construction Company put out debentures at 6 per cent. In the Eastern Company we have put out debentures at 4 per cent., and a large proportion has been taken up. I call this a remarkably good investment at 6 per cent., and I think the shareholders would do wisely to take it. If we could get to know who the present debenture holders are, they, with the shareholders, would be invited to take up the amount at 6 per cent.

A SHAREHOLDER: Would it be understood by a shareholder applying that he would be applying for a 6 per cent. debenture at par? Is there any objection to say how much is to be paid to the broker?

The CHAIRMAN: I cannot say that, as I have spoken to only one broker.

Mr. CHARLES BURT thought that Captain Pavy had put the matter very clearly.

The CHAIRMAN: You know now about as much as we do.

Mr. BAKER said the point he objected to was paying a broker £2,000 or £3,000, and then the shareholders applying for the debentures.

The CHAIRMAN: If we can get an idea that the whole of the debentures will be taken up by the present debenture holders and shareholders, we would not go near a broker at all.

Mr. BAKER: You cannot get them taken up unless you send out a circular.

The CHAIRMAN: Well, we must first have the power.

Mr. BAKER: Yes, but you ask for power also to pay a commission.

The CHAIRMAN: No, no. You must trust us to make the best bargain we can, or we are not worthy of sitting here.

Mr. GRIFFITH thought there was not much doubt as to the general policy of the Board. They were encumbered with the payment of a large amount of interest every year, and if they could reduce it, it was for the benefit of the Company generally that that should be done, and the shareholders ought to support the Board in carrying out such a policy. If the directors could let the shareholders have a large number of the bonds without paying a commission to a broker, he had no doubt that they would do so. On the other hand, it would not be wise to fetter the hands of the directors too tightly, as it was possible only a small number might be applied for by the shareholders. If they wished to lower the rate of the interest on the debentures they ought to leave a certain discretion in the hands of the Board to do the best they could for the Company, on the general understanding that the shareholders, if they came forward, should be treated quite as liberally as the broker himself.

The CHAIRMAN: Now, gentlemen, you have heard the statements on all sides. What we ask you to-day is to pass this resolution and to enable us then to deal with these debentures in a way which will prove best for the interest of the Company. If we do not place them in a satisfactory way, then we are here to be talked to. Those gentlemen who think we should have made a better bargain may depend on it that we shall endeavour to meet the general expression of opinion here to get the views of the shareholders on the subject. I think that is very important. I am not anxious to pay a high brokerage, but, at the same time, I am anxious to maintain the credit of this concern, and not to have our bonds hawked about in any way.

A SHAREHOLDER asked how long the bonds would have to run?

The CHAIRMAN: Twenty years. As I have said, we are only too glad to get an expression of opinion showing what the views of the shareholders generally are. I shall be very much disappointed if these bonds do not go off very fast at 6 per cent. If any shareholders present will tell us what amount they would like to take at 6 per cent. at par, we will take care of their interests.

Mr. BAKER said he could not get at what the intention of the directors was as to the brokerage—whether it was to be 1, 2, or 5 per cent.

The CHAIRMAN: We have not settled it. If you will take the £1[illegible]0,000 at 6 per cent. "firm," and allow us to send out to the shareholders offering them at the same price, you shall have the balance at the same price.

Mr. BAKER: At what price?

The CHAIRMAN: At par.

Mr. BAKER: But you propose to give a commission.

The CHAIRMAN: Nothing of the kind. What we are proposing to do is to ascertain the best terms at which we can make this bargain. We shall issue these bonds at 6 per cent. at par. We should send out to our shareholders, offering them all. They might take £50,000, £75,000, or £100,000, but any amount they do not take you shall have at the same rate.

Mr. BAKER: What do you propose to do with this broker?

The CHAIRMAN: I make that proposal to you. If you accept it, it will not be necessary to go to a broker. I have got a thing to sell, and you are a buyer. I tell you my price. If it does not suit, what will you offer?

Mr. BAKER: That is a question not to be gone into at a public meeting, but quietly [laughter].

The CHAIRMAN: I wish to bring you down to business. Now that I know your views, after this resolution is passed, you would be one of the gentlemen I would invite to come here and talk with me about the matter.

The resolution was then put and carried unanimously, and

The proceedings closed with a vote of thanks to the chairman.

---

## INTERNATIONAL ELECTRIC COMPANY (LIMITED).

The second ordinary general meeting of the shareholders in this Company was held on the 31st ult., at the offices, Copthall-buildings, Moorgate-street, under the presidency of Sir William H. Stephenson, K.C.B.

The SECRETARY (Mr. Frank Schloesser) read the notice convening the meeting, and the report of the directors was taken as read.

The CHAIRMAN said: I should like to add a few remarks to the report which has been laid before you, in further explanation of some matters touched upon therein, and also in connection with one or two matters to which no reference is made in the report. In the first place, as regards accounts, the expenditure may appear large, but it must be borne mind that, in a business carried on abroad, the salaries, travelling and other expenses, are necessarily higher than if the business were carried on in England. These circumstances, combined with the period of comparative inactivity caused by the Electric Exhibition, as mentioned in the report, have rendered the preliminary expenses of starting comparatively heavy. Furthermore, considerable time has been expended by the staff in the preparation of designs and estimates for important contemplated installations in designing improvements af apparatus. Some expense has also been incurred in carrying out experiments with new apparatus. The cost of all this has been put under the head of general expenditure for the present, but, inasmuch as it is almost probable that the installations, for which designs and estimates have been elaborated, will be carried out; seeing also that valuable improvements have been made in certain apparatus which are now being patented, a portion of the expenditure under this head will hereafter be carried to other accounts. And thus recouped, the directors believe that these circumstances combined with the facts and prospects they have been able to lay before the shareholders in the report, will satisfy them that the business will be of sufficient magnitude to justify the expenditure which has been incurred to obtain it. As regards the contracts which have been taken, a few particulars may be of interest to the shareholders. The Vienna Opera House contract is of a two-fold character. In the first place, it provides for the supply by the Company, against payment in cash, of all the interior conductors and fittings for the working of a minimum number of 3,850 incandescent lamps; and, in the second place, it provides for the supply by the Company of the current for the lighting of the house by means of engines and generating apparatus to be provided and fitted up, at its own cost, in the building. The minimum amount contracted to be paid to the Company for the supply of this current and maintenance of the whole installation is 61,000fl., or over £5,000 per annum. A proportional addition to this sum will be paid if the number of lamps is increased hereafter. The premises are prepared and placed at the disposal of the Company, without charge, by the Opera administration. The lighting contract is for a period of ten years, with an unconditional right reserved to the Company of renewing the contract for a further period of ten years. The contract reserves the right to the Company of supplying electric light to private consumers (approved by the administration) outside the Opera House, to the extent of 1,000 incandescent lamps, using the Opera House as a central lighting station. To any one acquainted with Vienna and the position of the Opera House, the value of the rights reserved to the Company of using the Opera House as a central lighting station will be apparent. As regards the Temesvar concession, the municipality binds itself to pay 30,624fls. (£2,552) per annum, for the supply of 730 street incandescent lamps during the usual hours for public street lighting. The Company has on its side contracted to put these lights into operation by the 1st September, 1884. In addition to the 730 lights, agreed to be paid for by the municipality under the terms of the concession, it is estimated that about 500 lamps, worked on the same plan, can be disposed of in flour-mills, spirit refineries, &c., which are required to be lighted the whole night through. The supply of light to other native consumers, which the concession also provides for, is a matter which will be dealt with as applications come in. Meantime, the existing gas company is using every effort to preserve the supply of gas to native consumers, and will be only too glad to be permitted to do so until it is convenient to us to take their place. As regards Roumania, a contract has been entered into with the Government for the supply, against cash payment, of the interior conductors and accessories for working 1,400 incandescent lamps in the new Royal Palace, Bucharest, now approaching completion. A tender sent into the commissioners of the Opera House at Bucharest for the internal fittings and conductors of the house has been recommended by them for acceptance by the council of Ministers. Definite proposals have been made by the administration of the Royal household, and are now under consideration of the board, for the lighting of the King's summer residence at Sinaia, in the

Digitized by Google

Carpathians, for which the conductors have already been laid by the Company. Negotiations are also proceeding for the sale of the conductors and internal fittings used for the experimental lighting of the old palace at Bucharest, and for the transfer of the lighting station to a Roumanian company. Other contracts of minor importance have also been entered into. The shareholders were informed some time ago that application had been made to the municipal authorities in Vienna for a concession for laying leads in the streets of Vienna. A decision in this matter was deferred by the municipality until the results of the Vienna Electric Exhibition were known. At the close of this exhibition the Austrian Government appointed a commission to report generally on the question of the terms on which such concession should be granted, and the matter was again deferred until this commission had made its report. The commission, which has not yet finished its labours, is composed of representatives of the various Government departments, of leading scientific men, and of representatives of the principal firms who exhibited at the International Electric Exhibition. The Company's managing director, Mr. Steuart, was appointed a member of this commission. As regards the scheme mentioned in the circular issued last May to the shareholders, for a combination with the possessors of certain electrical patents, and for a rearrangement of the Company's capital, it has been found that no arrangement advantageous to the shareholders could be come to. The scheme was therefore abandoned. I have pleasure, however, in informing the shareholders that the exclusive license for manufacture and use of the "Bürgin" dynamo machine has been secured for Austro-Hungary on advantageous terms. As regards the progress made with the more important contracts referred to, I may inform the shareholders as follows, viz.:—Concerning the Opera contract, the conductors, and fittings, and regulating apparatus for 400 lamps for the partial lighting of the stage, together with those for about 800 red and green lamps for use alternately with the white lamps, are already in the Opera House. This part of the installation was used for the experimental lighting of the stage undertaken by the Company, and forms part of the plant purchased by the administration. A 300 horse-power compound condensing steam engine, with the necessary boilers, has been built to the order of the Company, and is now in Vienna ready for fixing. As soon as this engine is in working the lighting of the stage will be commenced, and the lighting gradually extended to the rest of the house as the work proceeds. As regards Temesvar, the building for the central lighting station is in progress. A 240 horse-power compound condensing steam engine and two boilers have been purchased, and are now in Vienna waiting for the foundations to be sufficiently advanced to be sent to Temesvar. Two out of the seven No. 8 Brush machines which are to be used for this installation have been completed at the company's Vienna works, and five more are in hand. The insulators, and lamp and telegraph posts for carrying the conductors, together with a number of lanterns and accessories of various kinds, are also in hand, and some are ready for erection. As regards the new palace at Bucharest, the leads in the Queen's apartments have been put in, entitling the Company to a first instalment on account af the contract sum. The materials for the remainder of the work are on the spot, and will be fixed in place in about a fortnight's time. Now, gentlemen, I shall probably be asked how it is proposed to provide the necessary funds for carrying out the contracts into which the Company has entered. We propose the issue of mortgage debentures, secured on the uncalled capital of the Company, repayable, with a premium of 5 per cent., by annual drawings extending over twenty years, and bearing fixed interest at the rate of 5 per cent. per annum. The term of twenty years is adopted inasmuch as the returns from our lighting contracts are calculated to repay the capital outlay which they involve in that period. If a fair proportion of these debentures were taken up by the shareholders we think it probable that the remainder could be placed outside the Company. We propose to offer these debentures at par, and to give the holders a contingent bonus (in addition to the fixed interest) of 5 per cent., payable out of the surplus profits of the company after a dividend of 10 per cent. has been received by the shareholders. As regards outsiders, it is thought that these debentures ought to be attractive, having regard to the prospects of additional returns beyond the fixed 5 per cent. interest, coupled with the substantial manner in which the principal is secured. And as regards the shareholders, it will be seen that in subscribing for these debentures to an amount corresponding with the sums uncalled on their respective shares, they will be incurring no further liability, since the uncalled capital to the extent of the debentures issued could, in virtue of the trust deed, only be called up to pay off the debentures in the event of their not being repaid out of the general assets of the Company, and the shareholder would actually be receiving interest on the money so advanced. The success of this scheme must, as I have already suggested, depend altogether on the extent to which it is responded to by the shareholders, as it can hardly be expected that the outside public will give their support to the scheme unless they see that it is cordially adopted by the shareholders. Should this scheme not be accepted, we see no alternative but to have recourse to a further call. It now remains for me to submit the following resolution, viz.:—"That the report and accounts, as presented, be received and adopted." After dealing with this motion, we shall be glad to have the sense of the meeting on the projected scheme for raising capital. It has been suggested to us that some of our shareholders would feel better satisfied if the estimates and calculations of engineers in relation to the contracts taken were to be submitted to some independent authority for examination. I am prepared to say, on behalf of my colleagues and myself, that we shall be quite ready to follow that course if it should appear to be the general wish of the meeting.

Mr. G. BADEN-POWELL seconded the motion.

Mr. STEUART, in reply to a question, said the cash contracts embraced the one for the Opera House in Vienna; that amounted to about 150,000 florins. There was another contract for payment in cash at Bucharest, and the one the chairman had referred to. That made up, with a few smaller contracts, £13,000 payable in cash.

Mr. BAKER asked when they expected to receive a portion of the money for those contracts, or whether the portion of the money for the Vienna contract would be paid in full or in instalments?

Mr. STEUART replied that the Vienna contract provided payment of £8,000 within eight days of the imperial ratification; that was in respect to the apparatus used for the experimental installation, and which was to be purchased by the administration. As regarded the rest of the work, it was to be paid for monthly, as the work proceeded, for the internal fittings.

Mr. BAKER: When is it expected that the contract will be completed in its entirety?

Mr. STEUART: We expect to get the ratification almost from day to day. I can hardly say when it will be practically completed. The Imperial ratification is a matter of form.

Mr. BAKER thought they ought to fix a date for the actual completion of the work.

Mr. STEUART said the work would take twelve months to complete; but inasmuch as a part of it was already in working order, they would be receiving payment for the light which they could supply with the apparatus which was put in, and from month to month that would increase until at the end of the twelve months they would be in the receipt of the full £5,000 a year, or perhaps more if they increased the number of lights.

Mr. BAKER asked with regard to the arrears of call, £1,937, if any of that was due on the 8,000 shares issued to the vendor.

Mr. STEUART answered that all the calls on those shares had been paid up.

Mr. BAKER further remarked that £2,000 was put down for directors' remuneration, and the salaries and wages represented a total of £12,500. It appeared from the report they actually had in hand a sum of £55,000 after the Company was started; that included the additional 10s., which was paid afterwards, and out of the £55,000 no less than £12,000 had gone for salaries, wages and directors' remuneration. He thought it would be apparent to all the shareholders that this was a most excessive sum on the amount of capital paid up, and it certainly required some explanation. He thought they ought to have had details, and that the salary of the managing director should have been stated.

Mr. STEUART: The managing director's salary is £500 a year.

Mr. BAKER presumed he came in for a *pro rata* division in the £2,000 a year directors' remuneration. The salaries and wages covered a period of sixteen months, so that the annual expenditure in this direction was about £10,000. So far they had a sum of £7,600 from their lighting contracts, and he thought that if they compared their income, as far as they could anticipate what it was likely to be, the expenses would bear an alarming proportion. The brokerage on the issue of shares, £981, or 1½ per cent. on the shares issued, was excessive. The travelling expenses (£1,696) was a very large amount. With regard to the general policy of the directors, he was under the impression that the directors were about to form local companies, and supply the material from their own works. He did not know whether any local companies had been formed, or whether the directors were in treaty for their formation. He should be glad to know if they contemplated using the Ferranti and Thompson system. He also asked if the Company thought of issuing any capital in Vienna? He thought that if they could place any capital there it would give them a certain amount of standing. He also inquired if any land had been acquired in Vienna, and if so, what was the consideration paid for it?

Mr. STEUART replied that the salaries had been very heavy; but it must be borne in mind that salaries abroad were very high, especially in a place like Bucharest. They could not get people to go there at the same salaries as were paid in England. He thought they had a good deal to show in return for what had been paid. They had the contracts which were concluded, and a great many more which were almost certainties. There were a great many expenses in the way of salaries which were exceptional, and which would not be repeated, such as payments in connection with the putting up of their factory at Vienna, the purchase of engines, machinery, and so forth. As regarded brokerage, that was a matter that was agreed to be paid, and it was mentioned in the prospectus, and the directors were informed that what was charged was the usual rate. Arrangements had been made with the Ferranti Company, by which this Company would have an agency for the sale of that company's machines in Austria. They had also made arrangements for the use of one or two other patents, under which they paid a royalty, but no cash. With regard to local companies, it was a matter the directors had given a great deal of attention to, and they had been abroad several times for the express purpose of trying to form such companies, but the difficulty had been that nobody would move until the exhibition was over. He was in Vienna last November, and then things were just beginning to move, and there was a combination being formed for the purpose of taking up such installations as Temesvar, and working them—in fact to establish a working company like a gas company, and they were in treaty with those people to take these installations off their hands, because with their capital it would be impossible to retain all of them. He thought there would be some difficulty in getting any of their capital subscribed in Vienna. In Austria, he should mention, there was a great opening for the electric light. The street lighting was done by petroleum, which was very expensive, in consequence of the amount of labour it involved. The travelling expenses had been heavy, but three of the directors went abroad in order to acquaint themselves personally with the people they would have to deal with. They went as far as Bucharest, and were introduced to the King personally, and he thought their visit had a very good effect. He had been abroad very often, but had kept his expenses down as low as possible. They had contemplated buying lands in Vienna with the view of building a central lighting station, but when they found that the concession which they applied for for the laying of leads in Vienna would be deferred indefinitely, they thought that, seeing they were not very flush of money, they had better defer the question, and accordingly they did not buy any land.

Mr. MOSS moved, and Mr. SANDERS seconded, an amendment for the appointment of a committee of investigation to inquire into the expenses, and report whether the proposed new contracts were likely to yield a profit.

The CHAIRMAN replied that every information would be afforded to the shareholders at the office, and undertook that the new contracts should be referred to an expert to report upon.

Upon this the amendment was withdrawn, and the report and accounts were adopted.

A resolution to authorise the directors to issue £50,000 of debentures was withdrawn after some discussion, in the course of which several shareholders expressed the opinion that it would be desirable to make a call.

The retiring directors and auditors were re-elected, and the proceedings terminated in the usual manner.

## INDIAN AND ORIENTAL ELECTRICAL STORAGE AND WORKS COMPANY (LIMITED).

The adjourned general meeting of the members of this Company was held at the City Terminus Hotel on the 2nd inst., under the presidency of Mr. Ernest Noel, M.P.

The CHAIRMAN stated that the present was an adjourned meeting, the adjournment having taken place to see whether the committee which was appointed could obtain any alteration in the agreement between the Company and the parent company. He called on Mr. Bedford—understanding that that gentleman was the chairman of the committee—to read their report.

Mr. BEDFORD read the report, which stated that the committee proposed that the Electrical Power Storage Company should give up altogether the claim for £5,000, or, as an alternative, should agree to accept such amount by way of royalties as provided in the original agreement of sale and purchase. It was further suggested by the committee that proposals ought to be made by the Electrical Power Storage Company for the purchase back of the patents sold in May last. These proposals had been declined in a letter (embodied in the report and read). The position taken up by the Electrical Power Storage Company the committee regarded as most unsatisfactory. The committee had not had copies of various agreements supplied to them. They were therefore unable properly to understand the position of matters, but they were bound to say that they failed to see any real substantial benefit to this Company from the agreements which the directors had entered into. They asserted that it was impossible for any shareholder to have assumed from the notice issued on the 1st of July inviting them to the first statutory meeting of the Company that business of such importance as the consideration of an agreement was going to be brought before them, by which almost the whole of the working capital of the Company was going to be applied to an immediate redemption of the royalties, which could not have been expected to be payable for several years, and which, having regard to the present position of the Company, might never have become payable. The committee had been unable to ascertain the exact position of the accounts between the two companies. They thought it a pity that the usual profit and loss account did not accompany the directors' report. They had, however, ascertained sufficient to lead them to believe—if the accounts between the two companies were properly taken and the Storage Company's charges were disallowed for improper batteries supplied—that, instead of this Company owing the Storage Company a sum of £5,000, the account would be on the other side. The committee advised the shareholders to decline to pass the directors' accounts until a profit and loss account, together with necessary explanations and copies of all agreements, had been furnished to them, and they suggested the adjournment of the meeting.

The CHAIRMAN thought that the committee had treated the directors with very scant courtesy in not supplying them with a copy of their report, as he had thus been placed in an awkward position in making any statement with reference to it. He objected to some of the statements in the report, as they were not correct. As to the agreements, the directors had no objection to let the committee have copies, for they had nothing whatever to conceal. They had no objection to the continuation of the committee, and in fact they thought it would be better for some of their body to go on the Board, and then they would have absolute information on all points. He advised the shareholders not to acquiesce in the suggestions of the committee, as it would be fraught with mischief to their own interests.

Mr. BRAITHWAITE (a member of the committee) spoke of the necessity of the shareholders being supplied with a proper profit and loss account, and he argued the agreements ought to be carefully looked into. He suggested the adjournment of the meeting for these purposes.

Mr. BEDFORD advocated an adjournment of the meeting for three weeks, and thought that the directors ought cheerfully to accede to such a proposal, as there was a division in their own body.

Major STRUTT (managing director) thought the shareholders ought to have a committee of investigation.

The SOLICITOR pointed out that an adjournment of the meeting for three weeks would be too long, and the parent company would be in a position to recede from the agreement of the 13th December, under which they had agreed to defer their dividend, and to assign their Indian rights for M. Philippart's patent.

Mr. COLLET (general manager of the Electrical Power Storage Company) stated that his Company intended to stand by the agreement as it was.

Mr. BRAITHWAITE regretted to hear such a statement, as it showed discourtesy.

Mr. COLLET retorted that it was because of the discourtesy which had been displayed that his Company had decided to take their stand. They were willing to deal with the directors.

The CHAIRMAN stated that the committee were annoyed with the directors for having made an arrangement by which they had obtained the Faure patent, without which they would not have been able to resist M. Philippart's action in India at all. To lose the patent of M. Philippart would be a very serious loss for the Company. As to what was done at the statutory meeting, he did not mean to say that a resolution was passed, but he maintained that after the announcement that an important statement would be made at that meeting, the arrangement was fully and thoroughly explained to a very much larger number of the shareholders than had assembled on the present occasion, and that they apparently, by their silence as regarded any resolution, and by the speeches made at the time, approved the action of the directors. The prospectus, with the agreements, was submitted to Mr. Braithwaite's firm before it was brought out.

Mr. BRAITHWAITE said he had never seen the agreements.

Mr. COLLET asserted that he himself took the agreements round to Mr. Braithwaite's firm.

The SOLICITOR, at the request of Mr. Braithwaite, read certain clauses in one of the agreements, on which

Mr. BRAITHWAITE contended that certain matters in the agreement had been omitted from the prospectus.

Mr. COLLET stated that if it were shown that it was the *bonâ fide* request of a large number of the shareholders that there should be an adjournment of the meeting his company would consent to that course; but he contended that those who wished for the adjournment did not represent the general feeling of the shareholders.

Mr. BEDFORD stated that they represented shareholders to the extent of 10,000 or 12,000 shares, which, though certainly not a majority, was a very respectable minority; and they believed they were acting rightly and in the interests of the shareholders.

Mr. BRAITHWAITE stated that if the directors would let the committee have copies of the agreements in two or three days they could prepare their report in a fortnight, and the profit and loss account could be furnished at the adjourned meeting.

The CHAIRMAN stated that there were not the materials for a profit and loss account. They had not received them from India, and they could not make a profit and loss account till they knew the number of batteries handed over. If none had been handed over that could be shown to be in perfect order, then, under the arrangement made, they would owe nothing. If, on the contrary, it could be shown that they had received from the parent company a number of batteries in perfect working order, they would have to pay for those. They had handed them to the Eastern Company, from whom, in that case, a profit would be due to this Company. That was the only possible profit and loss account that could be shown. He suggested that they should adjourn the ordinary meeting for a fortnight, not passing the report or accounts, and that they should then proceed at once to hold the extraordinary meeting. Ultimately this suggestion was agreed to, and the extraordinary meeting was held. Continuing, the chairman moved the following resolution:—"That the directors be, and they are hereby authorised to accept the surrender by the Electrical Power Storage Company (Limited) of the 5,000 fully-paid shares, numbered 30,001 to 35,000, both inclusive, now held by them, and to issue in lieu thereof 5,000 deferred shares, such as hereinafter mentioned. And that of the 80,000 shares forming the original nominal capital of the company, 10,000 shares shall be deferred shares, and the remaining 70,000 shares shall be ordinary shares, and that the deferred shares shall not be entitled to dividend in any year until a dividend of 5 per cent. for that year and every previous year as from the 31st December, 1883 (or from the issue of the ordinary shares as to any issued subsequent to that date), shall have been earned upon the ordinary shares, but when such dividend of 5 per cent. shall be earned as aforesaid, the said 10,000 deferred shares shall be entitled to receive out of remaining profits a 5 per cent. dividend, and after provision for same, to participate for dividend in the residue of the profits equally with the ordinary shares, upon the full amount credited as paid upon the said deferred shares."

Mr. BULLIVANT seconded the motion, observing that it was simply accepting from the Electrical Power Storage Company a new patent for nothing, which they were advised and believed was better than they had bought. They were also asking that company to defer—and they had agreed to defer—the dividend on their shares till the shareholders of the Company received 5 per cent.

The resolution was then passed, and the meeting terminated.

## NOTES.

CABLE REPAIRED.—The cable between Falmouth and Bilbao is now repaired.

GERMAN UNION TELEGRAPH COMPANY.—This company notifies an interim dividend of 5s. 9d. per share.

HOTEL LIGHTING.—It is stated that electric lamps are to be introduced into the Royal Hotel, Blackfriars.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended January 4 amounted to £2,635.

APPOINTMENT.—Mr. Arthur Kitson has been appointed superintendent of the Maxim Electric Light and Power Company, of Philadelphia.

TILBURY DOCKS.—The contractors for these docks, Messrs. Kirk and Randall, of Woolwich, want tenders for lighting the works during construction.

LECTURES.—Mr. Bruce, of Oxford, is about to deliver a series of popular lectures on electricity and its applications in some of our provincial towns.

GLOBE TELEGRAPH AND TRUST COMPANY.—This company notifies dividends, in respect of the quarter ending 18th inst., of 3s. on the preference and 2s. on the ordinary shares.

ELECTRICAL CONDUCTORS.—The adjourned discussion on Mr. Preece's paper on "Electrical Conductors," will be resumed at the Institution of Civil Engineers on the 15th inst.

WASHINGTON UNIVERSITY, U.S.A.—The directors of this university have created a new chair of dynamic engineering, which will include electrical as well as mechanical engineering.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of December, 1883, are £1,461, against £1,346 in the corresponding period of last year.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company for the month of December, 1883, amounted to £33,030, and to £31,617 for the corresponding period of 1882, being an increase of £1,413.

THE ELECTRIC LIGHT IN THE COUNTRY.—Crompton arc lamps are to be used at Greenham, near Newbury, Berkshire, to light the workmen at night when reconstructing Messrs. Bagge's stores, which were destroyed in the last gale.

THE JUBILEE OF GERMAN TELEGRAPHS.—Germany this year celebrates the jubilee of the establishment of the electric telegraph in her borders. In 1833 Gauss and Weber, of Gottingen, erected the first telegraph line in Germany.

OVERHEAD WIRES.—Sir Charles Dilke was to receive a deputation of owners of property and others respecting overhead wires erected by telegraph and telephone companies yesterday (Friday), at the offices of the Local Government Board.

THE TELEPHONE IN NEW SOUTH WALES.—Telephone communication has now been completed between Maitland and Morpeth. The offices of the Steam Navigation Company are now connected with several commercial houses in West Maitland.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 4th January, 1884, were £2,125, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

VERY AMATEURISH.—A correspondent of an American paper wants to know "what is the best metal to use for insulating electric wire, and how applied?" This is almost on a par with the man who wanted to short-circuit a couple of wires with an office ruler.

THE EDISON SYSTEM IN BERLIN.—According to a French paper the German Edison Company have entered into an agreement with the Berlin Municipal Authorities, the result of which will be a considerable extension of this system of electric lighting in that city.

HENLEY'S TELEGRAPH WORKS COMPANY.—We are requested to state that the liquidation of the North Woolwich Telegraph Works Company in no way affects W. T. Henley's Telegraph Works Company, which carries on its business at North Woolwich as heretofore.

LIGHTING BY PRIMARY BATTERIES.—It is stated that electric lighting will shortly be tried in the saloon carriages on the South-Eastern Railway, and that the plan to be adopted is an improvement upon the principle experimented with in the carriages of the Great Northern line.

THE INSTITUTION OF CIVIL ENGINEERS.—Arrangements have been made for meetings of students on four Friday evenings during the session at seven o'clock. Amongst the papers to be read at these meetings is one by Mr. W. H. Preece, F.R.S., on "Some Elementary Electrical Notes."

A SEVERE THUNDERSTORM.—The latest news from the colonies says that the town of Invercargill, New Zealand, and surrounding district have been visited by a terrific electrical storm. Three persons in different localities were struck dead by lightning, and several others sustained severe shocks.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company in December, 1883, were £18,280. For the period 1st January to 31st December, 1883, they amounted to £255,080, against £241,373 for the corresponding months of 1882 and £234,850 for the same period of 1881.

UNIVERSITY COLLEGE, BRISTOL.—The next term at this college will begin on the 17th inst. Lectures in experimental physics are given by Professor Silvanus P. Thompson, and there is a physical and electrical laboratory attached to the college. Further particulars can be had by applying to the registrar at the college.

TENDERS WANTED FOR ELECTRIC LIGHTING.—Tenders are required for lighting the premises of the London and Provincial Steam Laundry Company, Battersea Park-road, S.E. Particulars can be obtained at the works, between the hours of 10 and 12, any morning. Tenders are to be addressed to the managing director by the 15th inst.

ANOTHER REMARKABLE WEEK.—In last week's Notes we recorded the fact that during the week ending December 29 no sunshine was registered at Greenwich. Again we have to state that, according to observations taken at the Royal Observatory, Greenwich, the "registered sunshine" from Sunday, December 30, to Saturday, January 5, was "*nil*."

ELECTRIC LIGHT IN BOSTON POST OFFICE.—The Edison Company for Isolated Lighting have closed a contract with the United States Government for lighting the Boston Post Office with their system of incandescent electric lighting. The plant will consist of 500 Edison lamps of 16 candle-power each, with dynamos and engines for producing current for same.

THE FISHERIES EXHIBITION.—The Commissioners appointed by Her Majesty's Government have, upon the recommendation of the International Juries, awarded a diploma of honour to Mr. Charles Lever, of Culcheth Hall,

Digitized by Google

Bondon, Cheshire, for special services rendered in lighting the dining rooms, &c., at the late Fisheries Exhibition by his arc lamps.

THE TELEPHONE IN QUEENSLAND.—Now that the required number of subscribers has been received for the Telephone Exchange, the Government have issued the necessary instructions for stretching the wires, &c. Messrs. Saber Brothers have been appointed agents for the Edison-Bell telephones, this being the sort principally in use in Brisbane and Maryborough.—*Colonies and India.*

ELECTRIC LIGHTING IN NANTES.—Electric lighting is progressing in this French town. The soap works of Messrs. Serpette, Lourmand, Larrey and Co., are lighted by a Serrin arc lamp and forty Swan lights; M. Moreau's factory by one Serrin lamp; M. Lotz's workshops by five Swan lamps; and those of the Chautiers et Ateliers de la Loire by eighteen Gramme arc lamps, two Serrin lamps, and 115 Swan lamps.

FESTIVITY.—Yesterday evening (Friday) the first socail gathering of *employés* at work in the electric lighting interest in Glasgow, was to be held in Victoria Halls, West Regent-street, in that city. Mr. Charles T. Grant, of the Scottish branch of the Edison Company, was to take the chair. We hope the gathering may prove a success, and become an annual institution. We are great believers in these social gatherings, and are glad to see a move made in this direction in Glasgow.

WOUND UP.—Messrs. Ferranti, Thompson, and Ince (Limited), the Birmingham and Warwickshire Brush Electric Light and Power Company (Limited), and the Yorkshire Brush Electric Light and Power Company (Limited), have all resolved to wind up voluntarily. Mr. Latham is appointed liquidator in all three cases, and is to take the necessary steps for carrying out the agreement with the Hammond Company relating to the amalgamation of the three companies with the latter.

THE ELECTRIC LIGHT IN CHURCH.—At the Catholic Church, Bournemouth, on Christmas Day, the representation of the "crib" was considerably enhanced by the introduction of an electric lamp amidst the rock-work. The lamp gave the appearance of a star, and illuminated the interior of the cave with an appropriate intensity of light. The effect was greatly admired by the crowds which visited the church at the benediction service on Christmas Day. The electrical arrangements were carried out under the personal direction of Mr. Eric S. Bruce, M.A., Exeter College, Oxford.

IN LIQUIDATION.—According to the *Gazette* for the 4th inst., Mr. Arthur French St. George, of No. 20, Bucklersbury, E.C., and Radnor House, Redhill, Surrey, electrician, late of Nos. 21 and 29, Finsbury-pavement, E.C., the White House 18, Telegraph-street, E.C., 40, Southampton-buildings, Chancery-lane, and Thistlecroft, Hersham, Walton-on-Thames, Surrey, has instituted proceedings for liquidation of his affairs. The first meeting of creditors is to be held at the offices of Messrs. Geo. Davis, Son, and Co., No. 80, Coleman-street, E.C., solicitors, on the 15th inst., at 2 p.m.

THE ELECTRIC CARBON STORAGE, &C., COMPANY'S SALE.—Some curious contrasts in the prices paid for various articles came out on the occasion of the recent sale of the effects of the Electric Carbon Storage, &c., Company, of Leith. Thus, full size storage cells, complete in all respects, went for from 5½d. to 6½d. per cell, the original price being nearer £2. The Higgs compound dynamos, made by the company, sold for from £5 10s. to £6 and over. The highest price realised for dynamos was, we believe, about £13. Covered wire sold at almost equally low prices, as did other portions of the plant and stock. The tools, on the other hand, realised equally high prices, far above what they ought to have cost.

ELECTRIC LIGHT FOR RAILWAY WORK.—Five arc lights have been erected in the principal cutting on the new Saddleworth and Stalybridge branch now being constructed for the London and North-Western Railway Company. Owing to these lights the contractors are enabled to work night and day. The plant consists of a dynamo driven by a Marshall engine and about one mile of cable supported on poles. Each lamp has a special hood for deflecting the rays. The installation has now been at work for three months, and has, we are assured, proved very successful. The work was carried out by Messrs. F. B. Welch and Co., electric light contractors, of Manchester-chambers, Market-street, Manchester.

ACCUMULATOR PATENTS IN AMERICA.—We take the following from the *Electrical World*:—"In the case of Jablochkoff *v.* Brush, with regard to the secondary battery as applied to the electric light, heard before the examiner of interferences, the interference has been dissolved. Brush established by evidence that the device had been in public use for over two years. In the case of Crompton *et al. v.* Brush, also respecting secondary battery, in which the plaintiffs relied on a foreign patent, a decision has been given in favour of Brush. An application has been refused to extend the time for taking testimony in the cases of Keith, Shaw, and Brush *v.* Faure, and Keith, Shaw, Maloney, and Brush *v.* Faure."

ELECTRIC LIGHT IN THEATRES.—The Hammond Electric Light Company have just successfully completed installations of the incandescent light at the Prince of Wales's and Royal Theatres, Birmingham. Ferranti dynamos are employed, and supply current to Swan's 123-volt lamps of 20 candle-power nominal, but here run at about 25 candles. The auditorium and stage lights are very efficiently controlled from the prompter's corner, and are found a great improvement upon gas, noticeably in the better ventilation and greater freshness and coolness of the air, even with crowded houses. Hearty applause greeted the lights when first turned on. The installations are under the charge of Mr. T. H. Seymour Hawker, district electrician to the company. We may perhaps give fuller details of this installation later on.

A NEW TELEPHONE.—Experiments were made recently, says an American paper, on the large wire of the Postal Telegraph Company between New York and Meadville, Pa., a distance of 509 miles, with a telephone devised by Professor Webster Gillett, of Ypsilanti, Mich. What Professor Gillett calls a 10-point instrument was used. He uses in his transmitter a needle attached to a rubber disc, coming in contact with granulated carbon, held under compression to increase the conductivity. Each point is like adding another telephone in power. The feature of the receiver attached to the telephone is the increased magnetic surface presented to the diaphragm. Chicago, a distance of 1,010 miles, including a cable containing 22 wires, has been reached satisfactorily with the 10-point instrument. The single-point instrument has been operated for from 75 to 100 miles. The 10-point instrument was during the experiments reduced to six points, and communication was still kept up.

ELECTRIC LIGHTING IN TARTARY.—The electric light has recently invaded the steppes of Tartary. An installation has just been fitted up by Mr. D. Macdonell, acting for Mr. Hornsted, British Vice-Consul at Moscow, and agent in

Digitized by Google

Russia for Messrs. R. E. Crompton and Co., in the Samara Sugar Estate and Refining Company's factory and workshops at Timachevo. The installation consists of three C Bürgin machines (one of which is spare), working 84 twenty-candle Swan lamps; 42 lamps are in the factory, the other 42 are divided between the workshops, &c. The machines are driven by a 50 horse-power turbine, which also drives a flour mill and the workshop tools. All the fittings, &c., had to be made at Timachevo, nothing being sent but machines, lamps, and wire. The correspondent who sends us the above information adds that "the Russians show little surprise at the light—they seldom do at anything; but the Tartars are greatly astonished, and can't make it out at all."

THE LIGHTING OF LIGHTHOUSES.—The committee appointed to conduct experiments with illuminants for lighthouses visited Dover on Wednesday, and proceeded to the South Foreland lighthouses to make the final arrangements. The committee consisted of Captain Sydney Webb, Deputy-Master of the Trinity House; Captain Nisbet, Captain Weller, Captain Burns, Captain Goyan, Sir James Douglass, Mr. Inglis, and Mr. Price Edwards. After inspecting the machinery and the preparations made, ranges were selected inland to a distance of three miles as lines of observation, along which measurements and the relative tests of oil, gas, and electricity will be made at night—especially in foggy weather. The proceedings are likely to last for several months, and will be of a very interesting and important character. Three massive wooden towers have been erected along the cliff, in which lanterns are to be placed. One of these will be devoted to electricity, another to gas, under the care of Mr. Wigham, the exponent of the system of lighting as exhibited in the Irish lighthouses, and the Trinity House mode of using oil will be experimented upon in the third.

THE "MONTHLY CORRESPONDENT."—We have just received the second issue of the *Monthly Correspondent*, a journal organised by the Madeira staff of the Brazilian Submarine Telegraph Company, and dedicated to its staff. From the contents we should say that the idea has been heartily taken up by the wide-scattered staff of the company, and that the editor of the *Monthly Correspondent* will have no difficulty in obtaining matter for this latest literary venture. The contents for this month are as follow:—"A Few Words of New Year Greeting" from the Editor, whose references to P. K. and its probationers will, perhaps, awake more echoes of the past in some minds than he is aware of; then we have a dialogue between a superintendent of a station and a newly-arrived probationer, in which a considerable amount of elementary instruction in telegraphic matters will be found; sundry notes as to the duplication of the company's cables, "A Celestial Visitant," "Doings at St. Vincent and Madeira," "Personal," and a capital poetic effusion, which we reproduce in another column. Perhaps there is no station in the world where the *M.C.* will be more heartily welcomed than St. Vincent, though it will, doubtless, be greatly appreciated elsewhere. We congratulate the editor and contributors upon the results of their united energy.

AN AMUSING NEW YEAR'S CARD.—We have received a very amusing New Year's card from the Edinburgh Branch of the National Telephone Company, a copy of which has, we are informed, been sent to all the subscribers of that branch. It represents the "Private Bill Posting Station of the National Telephone Company, Limited," which consists of a hoarding in front of a house that is being rebuilt. Over the top of the hoarding one gets a glimpse of the roof of the exchange, with its collection of wires. The fun of the idea lies in the grouping of the bills pasted on this "private station." The designer has evidently posted himself in fron of some of the many conglomerations of advertisements to be found in our large towns, taken the heads or tails, as the case may be, and made them read on. Thus we are gravely told that "Beecham's Pills are warranted to cure Henry Irving in the Bells;" or that "Families Removing Eno's Fruit Salt will find it a good plan to join the Telephonic Exchange;" or again, "The Telephonic Exchange is the best route to the Continent *viâ* Telephone Steam to Canada and the United States." These combinations are brought about by the supposed pasting of one bill over another, an old device of the comical card designer, but none the less amusing in the present case. We believe it to be an open secret that the card was originated by Mr. Watson, of the National Company's Edinburgh Exchange.

SONG OF THE TELEGRAPH CLERK.—(With respects to W S. Gilbert, Esq.)—

When the soft point of your pencil keeps a-breaking—keeps a-breaking,
And your time to say the least of it is spare—it is spare,
Or those everlasting signals get a-shaking—get a-shaking,
And you feel a strong propensity to swear—ty to swear;
While Reuters keep your leisure time curtailing—time curtailing.
And P.B. advises more work coming on—coming on,
And patience, sight and ink all seem a-failing—seem a-failing,
Oh a T.C.'s lot is not an easy one! No!
With a lot of Western "backwork" coming on—coming on,
A T.C.'s lot is not an easy one!

When you find the other station is a-calling—is a-calling,
And you've just begun to roll a cigarette—a cigarette,
And he says your inattention is appalling—is appalling,
And you feel the matter isn't ended yet—ended yet;
When the fellow at S. Vincent loses patience—loses patience
And requests another man to be put on—be put on!
Tho' 'tis useless to indulge in execrations—execrations,
Oh a T.C.'s tongue is not a heavenly one! No!
There's not the slightest reason 'neath the sun—'neath the sun,
To call a T.C.'s tongue a righteous one.

When the clock strikes 5:30 in the morning—in the morning
And the Seven Sleepers all are fools to you—fools to you,
And you seem to bolt your pencil in your yawning—in your yawning,
And nearly knock a tooth out as you do—as you do;
When anxiety for rest begins to tweak you—gins to tweak you,
And your sleepiness is anything but fun—thing but fun,
And it seems a hopeless matter for the B.Q.—for the B.Q.
Oh a T.C.'s life is not a rose-leaf one! No!
Taking these considerations, as we've done—as we've done,
A T.C.'s life is not an idle one!

C. R. C. in *The Monthly Correspondent*, Madeira.

THE ROYAL INSTITUTION LECTURES.—In the course of his concluding lecture on "Alchemy in Relation to Modern Science," delivered at the Royal Institution on Tuesday, Professor Dewar said:—"At the beginning of the century it was discovered that electricity could be employed to decompose bodies in the same way as fire had been employed for the purpose, but electricity was a far more convenient agent. The resolution of water by electricity into its two component gases, and the coverse experiment, were here performed. Sir Humphry Davy applied this method, and showed that soda, which had been regarded as a kind of elementary body, though it was supposed that it might prove to be a body like the calxes of the metals, was a compound body.

Digitized by Google

Davy's experiment on soda with electricity was exhibited. Davy carried the investigation further, and showed that salts resolved themselves either into a metal and something else, or into an alkaline body and somthing else. Thus, metals could be decomposed and recomposed, like water. On the subject of electricity, the professor said that a small amount of electrical heat was equal to an enormous amount of mechanical power; and he demonstrated the intensity of electric heat by showing a platinum wire incandescent, and by fusing copper in a crucible, the metal not only being melted, but boiling. By electricity metals could be heated to a much greater temperature than in any furnace, and if the metals could not be separated, it might at least be discovered if they had in their particles the same kind of motion. There was reason to believe that every kind of matter, if only heat enough could be applied, could be got into the gaseous state. At that high temperature they all emitted light, and the kind of light was characteristic of the matter, so that all that was required was an instrument to enable them to recognise the kind of light given out. This instrument was the prism."

Electric Lights in Lighthouses.—In a recent lecture, delivered at Sunderland, Mr. B. Morton, superintendent of lighthouses for the north-east coast, gave the following figures relating to the intensities of various lamps now in use. The standard of comparison was a Fresnel four-wick lamp, and fixed dioptric lens, which was supposed to give a light of 100 candles.

*Dioptric Lights—Relative Intensities.*

| | Candles. |
|---|---|
| 1. Fixed dioptric light, 4-wick lamps ..... | 100 |
| 2. Fixed dioptric light, with 6-wick lamps ... | 220 |
| 3. Revolving (six sides) 6-wick lamps (Start) | 1,887 |
| 4. Double-flashing 6-wick lamps single apparatus ..... | 1,245 |
| 5. Double-flashing ditto, double apparatus... | 2,560 |
| 6. Electric fixed (South Foreland) ..... | 1,691 |
| 7. Electric fixed (Lizard) ..... | 3,783 |
| 8. Electric revolving (Souter) ..... | 7,797 |

Commenting on these figures, Mr. Morton said that "startling as these figures are, they showed how great had been the progress, not only in improving the power of the lamp, but, still more, how enormously the power of light had been increased by means of the more perfect lenses that were now fitted in lighthouses. The power of the electric light at Souter Point was 1,520, maximum power 3,040; at Foreland, 3,040; at the Lizard, 3,620 and 8,250. Although the power of the electric lamp at Souter was much less than the one employed at the Lizard, yet, owing to Souter being a revolving light, the power of the beam is about twice that of the Lizard." After comparing the lights now used with that employed in Smeaton's first Eddystone Lighthouse, Mr. Morton went on to say:—"I may state that the Trinity House is about to erect on St. Catherine's Point, Isle of Wight, an electric light produced by a De Meritens dynamo. When one machine is at work the light will be equal to 30,000 candles, or about twenty times the intensity of the electric light at Souter Point; and when the two are employed the intensity will be equal to 60,000 candles, which, when assisted by the optical apparatus, will be a blaze of light of extreme brilliancy, and yet it is conjectured, under similar circumstances to Smeaton's when seen at one mile (viz., in foggy weather) St. Catherine's will be visible about five miles."

The Electro-chemical Energy of Light.—M. Griveaux has been making some researches on this subject. Instead of measuring the current developed, he measures the electromotive force. He makes use of Clark's potentiometer method, and employs as a battery for comparison the Latimer Clark standard cell, this being placed in an open circuit, as well as the battery formed by plates of sensitised silver, immersed in acidulated water. The battery employed in the closed circuit is a Daniell. The three batteries are surrounded by melting ice, to prevent the disturbances arising from variations in temperature. A Lippmann electrometer, placed in the circuit of the photo-chemical battery, serves for the measurements; a Ruhmkorff galvanometer in the circuit of the Clark cell enables the apparatus to be more readily regulated. The two resistances—the relation between which should give the relation required between the electromotive forces—are obtained by two Pouillet rheostats, having identical platinum wires. The rheostat in the circuit of the Danieli battery, and which should give the arbitrary resistance, has a scale graduated in centimetres. That in the circuit of the silver battery has a scale divided into millimetres, along which slides a vernier for marking tenths, which carries a cup full of mercury, into which the wire passes. The plates are of pure silver. To obtain a deposit of silver salt on their surface of constant thickness, great precautions have been taken. The plates are immersed as positive electrodes in a solution of one-tenth of bromide or iodide of potassium; they are kept always at the same distance from the negative electrode, made of a platinum plate of equal surface. The current is furnished by a Daniell cell, charged with a saturated solution of sulphate of copper and an equally saturated solution of sulphate of zinc; these solutions are always filtered before using. The battery is not mounted until the moment it is required, and the liquids in it are renewed, as well as the solution of iodide or bromide of potassium in the trough and at each new operation. The battery and trough are placed in the melting ice. The wires which connect the silver plates to the battery poles are thick and short, and their resistance may be neglected by comparison with that of the liquids in the trough and of the battery. Owing to the precautions taken, it is admissible that the circuit traversed by the current always offers the same resistance, whilst the E.M.F. of the battery does not vary. The current also does not vary, and, by allowing it to flow for similar lengths of time, the same deposit of salt of silver is obtained. M. Griveaux announces that he has set himself to solve the following questions:—Given the same plate, and the same luminous source, what influence does the distance between them exert? The comparison of different sources to ascertain their luminous power and electro-chemical energy? What influence does the superficial area of the sensitised plate exert, and what is the thickness of the deposit of silver salt? What effects are produced by the same quantity of light falling on plates of different area, but of identical formation? The influence exerted by the character of the light, and, lastly, the relation between the electromotive force developed, and the length of wave of the simple light employed? M. Griveaux promises to communicate the results to the French Academy of Sciences when his observations are completed.

Edward Davy.—The graphic and interesting accounts of Edward Davy's telegraphic inventions, which have appeared in these pages from the pen of Mr. J. J. Fahie, have aroused considerable interest in the colony of Victoria, Dr. Davy's adopted home. We notice that Mr. Ellery recently read a paper before the Royal Society of Victoria in which he concurred with Mr. Fahie in thinking that, if Davy had stayed in the Strand instead of emigrating to Australia in disgust, he would have succeeded in establishing his claim to be the first inventor of the electric telegraph. At the conclusion

Digitized by Google

of his paper, Mr. Ellery proposed that the society should do him such honour as lay in their power by electing him a life honorary member. The meeting, however, were of opinion that Dr. Davy deserved some still better recognition of his so long neglected genius, and appointed a sub-committe to report upon the best means of doing him public honour. We hope that our colonial kinsfolk will not be allowed to entirely show us the way in this matter. Davy lived in London, and exhibited his apparatus here long before he went to live in Australia. Who can tell how much modern telegraphy is indebted to the inventive genius of the chemist who resided at 390, Strand? Had he stayed here he would no doubt have exercised a very powerful influence on the history of the telegraph, for, as Mr. Fahie has so ably shown, he was far in advance of his contemporaries both in theory and practice. Circumstances caused him to leave us, and he was for a time forgotten. Do not let us forget how much he is deserving of honour at our hands, however—not a mere empty, formal, and official recognition of his services, but something substantial, and that may prove of benefit to the man himself in his declining years. Why not place his name on the Civil List, as has been already suggested? There are many far less deserving than Dr. Davy to be counted in this list. We feel sure that the many telegraph engineers and electricians of the present day who know how to appreciate Davy's genius will not allow their colonial brethren to out-do them in honouring him, nor let the matter sleep for want of a little energy. It is curious to notice that Dr. Davy was not altogether fortunate in his Australian career, and that misfortune came upon him through no fault of his. It appears that Dr. Davy was Assay Master at the Melbourne Mint, from 1853 to 1855, and enjoyed a salary of £1,500. This was when Mr. La Frobe was governor. Dr. Davy had been specially invited to accept this post whilst occupying another similar, but less lucrative position in Adelaide. A succeeding governor, however, Sir Charles Hotham, abolished the office, giving Dr. Davy, by way of compensation, six months' salary. Here, then, was Davy once more turned adrift by Fortune's wheel. At the time that he was at Melbourne Mr. Childers, the present Chancellor of the Exchequer, was Auditor-General there. After this Davy tried his hand at farming, with but indifferent success, and finally settled down in Malmesbury to practise his profession of surgeon. Here he gradually rose high in popular esteem, has been several times mayor, and has been prime mover in several local public works of great benefit to the town. Dr. Davy is now in his seventy-seventh year, and is not so well able to carry on his profession as in his younger days, and from various causes his practice is not so good as it used to be, consequently a grant from the Civil List would be as good a mode of honouring him as any, and we think it ought to to be made.

A New York Lighting Station.—The last number of the *Electrical Review* of New York contains a description of the United States Electric Lighting Company's station in Stanton-street, New York, from which we take the following details:—The station supplies 26 circuits, of a total length of about 8½ miles. The station proper consists of a building 58ft. by 100ft. It is built of brick, with brown-stone trimmings. The boiler room is 54ft. by 47ft. Near the partition wall, which separates the engine room from the boiler room, are two large chimneys, which furnish the draft for the boilers. The flue in this chimney is 3ft. by 6ft., and 100ft. high. After leaving this room you enter the engine room. On one side of the engine room are located the engines, two in number. They are of the Corliss type, built by Watts, Campbell, and Co., of New York, N.J., and have given perfect satisfaction. These engines drive a 7-in. steel jack-shaft, which revolves at the rate of about 175 turns a minute. The belt used on this shaft is 60in. wide and 120ft. long. It is the largest belt in operation in New York, and the largest but one in the world. The power for the dynamos is taken from intermediate shafting driven from this 7-in. steel jack-shaft. The belts used on these intermediate shafts are respectively 36in. and 42in. in width. There are eight horizontal steel boilers, 66in. in diameter and 16ft. long. They were specially designed for this station. These boilers under a pressure of 85lb. to the square inch generate 125 horse-power each. In connection with the boilers there is a Berryman heater which feeds them with water of a temperature of 200deg. Fahr. There is no loss of steam in this instance, as the water is heated by the exhaust or waste heat from the engine. It should be said that the large engine is nominally of 500 horse-power, but has been run up to 600. Its main fly-wheel is 20ft. in diameter, 5ft. wide, and weighs 20 tons. The smaller engine is of 125 horse-power (nominal), but has easily run up to 200 horse-power. On a run of fourteen hours, the large engine was ascertained to consume, on the average, only 2⅝lb. of coal per horse-power per hour. Leaving the engine room you enter the lower dynamo room, 48ft. by 75ft. Through the centre of the room there is a passage way, and on both sides are located the machinery and dynamos, thus giving free access to all parts which may require inspection. In this room and the larger dynamo room overhead, there are 60 dynamos of 10, 15, 20, and 30 lights capacity each. The dynamo rooms are in charge of the dynamo superintendent, Mr. A. E. Scoullar. There are two lines of dynamos above and below operated by the large engine, one line above operated by the small engine. The circuits from the dynamos and from the outside lines are all brought to a large and ingeniously constructed switchboard, designed by Mr. Scoullar, by means of which the dynamos can be coupled together in any way desired. Any outside circuits can be coupled together, and any of the outside circuits can be coupled to any of the dynamos, and changed in very quick time from one battery of dynamos to another, and without affecting the others to an appreciable extent. The switchboard is also arranged so that the dynamos can be put on either engine. They can be readily changed from the night to the day engine. All the wires leading to this switchboard are encased in wooden mouldings in the ceilings overhead. This, besides being a very fine piece of joiner work, results in keeping the wires out of the reach of careless or maliciously disposed persons. The machinery is so designed that, in case of accident to one line of shafting, another can be at once connected by a system of clutches. The machines used in the Stanton-street station, for both the arc and incandescent lighting are of the same general type, the principal difference between them consisting in the winding of the armature and field coils, which is varied to produce the different qualities of current required. The current generated by these machines is continuous, and free from pulsations, thus rendering it less dangerous. In both the arc and incandescent systems, in the Stanton-street station, the regulation of the machine is entirely automatic. Lights may be turned on or off at will, and a corresponding change is at once made in the current generated and in the amount of power required for driving the dynamo. From the Stanton-street station 576 arc lights are fed, and a large number of Maxim incandescent lights. The company is operating three other similar stations in the city; one on East 44th Street; one on Fulton-street, near Greenwich; and one on Elm-street, near Reade.

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 175.)

**Separation of Ozone.**—Ozone is developed by electrolysis in aqueous solutions of nitric, hydrofluoric, sulphuric, or phosphoric acids, also in those of nitre, potassic phosphate, or sodic sulphate, but not in those of hydrochloric or hydrobromic acids, or in strong nitric acid, or in aqueous solutions of metallic chlorides, bromides, iodides, or ferrous sulphate. According to Houzean (*Comptes Rendus*, Vol. LXXIV., p. 256), the electrolysis of water furnishes only 3 to 5 milligrammes of ozone per litre (*Jour. Chem. Soc.*, Vol. X., 2nd series, p. 220).

**Electrolysis of Hydric Peroxide.**—$H_2O_2$. Molecular weight = 34. Electrolysis gradually resolves peroxide of hydrogen into hydrogen and oxygen, the proportion of the latter being greater than in the decomposition of water (Thenard).

E. Schone has electrolysed peroxide of hydrogen, and found that the results were influenced by the strength of the solution, the degree of acidification, and the strength of the current, and concludes that it is not an electrolyte, and that its decomposition during electrolysis of the water or acid present is a result of secondary action, due to the liberated hydrogen and oxygen (*Jour. Chem. Soc.*, Vol. XXXVI., 1879, p. 878).

According to Berthelot a dilute solution of hydric peroxide undergoes electrolysis in two different ways—viz., one with, and one without the evolution of hydrogen, and both of these may coexist. With high electromotive force both gases are evolved, but with low electromotive force, such as that of a zinc cadmium couple, only oxygen is given off, and no hydrogen gas appears at the cathode. The latter decomposition can be effected by any current, however feeble. In this case either the peroxide splits up into water and oxygen, or more probably a secondary action occurs, and the electrolytic hydrogen combines with undecomposed peroxide to form water.

**Separation of Nitrogen.**—N. Electro-chemical equivalent. $\frac{14}{3} = 4{\cdot}66$. A triad anion. It is set free (along with other gases) by simple contact of metallic zinc with ammonic nitrate in a state of fusion. A concentrated solution of ammonia, when electrolysed by a separate current and iron electrodes yields pure nitrogen at the anode, and hydrogen at the cathode (Hisinger and Berzelius).

The electrolysis of compounds of nitrogen and hydrogen will be treated of with the alkali metals.

**Electrolysis of Oxides of Nitrogen.**—The only ones of these which appear to have been thus treated are hyponitric ($N_2O_4$) and ordinary nitric acid ($HNO_3$). The former aqueous acid conducts slowly, and is decomposed (Faraday). W. Zorn prepares hyponitrites by the electrolysis of a solution of a nitrite by means of a current from four Bunsen cells and mercury electrodes, and stopping the current as soon as ammonia begins to be evolved. In this reduction hydroxylamine is also formed (*Jour. Chem. Soc.*, Vol. XXXVIII., 1880, p. 4).

Nitric acid when concentrated is a good conductor. It yields with platinum electrodes oxygen, and simultaneously becomes yellow and then red at the cathode, and finally evolves gaseous nitric oxide. A more dilute acid yields hydrogen at the cathode, the quantity being greater as the acid is weaker and the current more dense; and if the acid is not of greater specific gravity than 1·24, and the current not too strong, the water alone of the acid is decomposed, and the full equivalent quantity of hydrogen is set free as gas.

By electrolysis, concentrated nitric acid is decomposed with production of nitrous acid; with the acid of sp. gr. 1·2, a feeble current does not produce this effect. No ammonia is produced in dilute nitric acid, either *per se* or in presence of sulphuric acid, but if a solution of cupric sulphate is added in sufficient amount, sulphate of ammonium and metallic copper are simultaneously produced until all the nitric acid is converted into ammonium sulphate. In the presence of free alkali, nitrates are not converted into ammonia, but the latter is changed into nitric acid (C. Luckow, *Jour. Chem. Soc.*, Vol. XXXVIII., 1880, p. 282).

Brester states (*Chem. News*, Vol. XVIII., p. 144) that when decomposed by electrolysis nitric acid does not evolve any hydrogen gas at the surface of a cathode of platinum or charcoal; the acid is converted into ammonia. Bloxam (*Chem. News*, Vol. XIX., p. 289) has shown that the hydrogen set free from a cathode of platinum in dilute nitric acid, or in a solution of potassic nitrate, contained in a porous cell, placed in dilute sulphuric acid containing the anode, converts not more than one-half of the nitric acid of either of those solutions into ammonia. Bourgoin (*Comptes Rendus*, Vol. LXX., p. 811) has also electrolysed nitric acid.

The electrolysis of nitric acid, and solutions of its soluble salts with electrodes of wood charcoal or gas-carbon yield mellogen free from nitrogen (Bartoli and Papasogli, *Jour. Chem. Soc.*, Vol. XLIV., 1883, p. 592; *The Electrician*, Vol. X., p. 388, Vol. XI., pp. 28 and 101).

In the electrolysis of red fuming nitric acid no gas is set free at first at either electrode. At the anode, $NO_4$ is totally changed to $NO_5$ by oxidation. At the cathode, $NO_5$ is reduced to $H_3N$ during the whole of the electrolysis (A. Brester, *Chem. News*, Vol. XVIII., p. 145).

Finely divided copper, palladium, platinum, or carbon, charged with hydrogen, convert nitre into potassic nitrite and ammonia (Gladstone and Tribe, *Jour. Chem. Soc.*, Vol. XXXIII., 1878, pp. 306 and 307). Gladstone and Tribe have also investigated the electrolysis of a solution of potassic nitrate by a zinc copper couple, and are inclined to the hypothesis "that the two metals electrolyse the nitrate of potassium, with formation of nitrate of zinc, the reduction being effected at the negative pole through the agency of the potassium" (*Jour. Chem. Soc.*, Vol. XXXIII., 1878, p. 143). Professor Thorpe also has shown that the copper zinc couple, in the presence of water and saltpetre, converts the whole of the nitrogen of the salt, first into nitrite, and then into ammonia (*Jour. Chem. Soc.*, Vol. XXXIII., 1878, p. 139).

**Passive State of Metals.**—A peculiar condition, termed "the passive state," occurs with various metals when used as electrodes in nitric acid. By the following methods a platinum wire, to be used as the cathode in nitric acid of 1·49 sp. gr., and in which, with a suitable density of current, it would usually evolve gas for a time only, will be caused to evolve no gas from the moment of immersion. 1st. By connecting and then immersing the two polar platinum wires together in the liquid, and then at once separating them. (In this case, however, the acid must be diluted with less than its own volume of water). 2nd. By igniting the cathode, and then immersing it after the anode. 3rd. By taking a second platinum wire, and after the cathode has ceased to evolve gas, joining the wire to it outside the liquid, then immersing the wire and withdrawing the cathode. The fresh cathode will then evolve no gas from the commencement, and this property may be transferred by it to a third wire, and a fourth one, and so on. A wire which has lost the power of liberating hydrogen, recovers it by exposure to air, the time required being longer as the acid is stronger. In all these cases, if the current is too strong, gas will be evolved. (Gmelin's "Handbook of Chemistry," Vol. I., pp. 253-362. *See* also A. Brester, *Chem. News*, Vol. XVIII., p. 144.)

**Separation of Fluorine.**—F. Electro-chemical equivalent 19. A monad anion. I have made many attempts with this object by electrolysing anhydrous hydrofluoric acid, with anodes of carbon, platinum, palladium, and gold; also by electrolysing certain fluorides in a state of fusion. In none of these cases, however, was that element definitely obtained. These experiments will be briefly described under the headings of the respective substances.

**Electrolysis of Anhydrous Hyddrofluoric Acid.**—H.F. Molecular weight = 20. I have examined this highly dangerous and extremely volatile liquid. It boils at 67 deg. F. Potassium immersed in the chilled acid evolved hydrogen, and

Digitized by Google

produced vivid combustion. Sodium acted as it does upon water. The noble and base metals did not decompose it. Magnesium, aluminium, zinc, cadmium, tin, lead, reduced iron, powdered arsenic, antimony, or bismuth, did not expel hydrogen from it.

I electrolysed the chilled fuming liquid by means of a separate current with a platinum anode; it conducted much more readily than pure water. With four Smee elements it began to conduct visibly, and with ten it conducted readily. No odour of ozone was evolved. The anode gradually acquired a thick red-brown crust, which deliquesced in the atmosphere. With forty elements the conduction was copious, the anode rapidly corroded, and much finely-divided platinum collected in the liquid. The brown coating was insoluble in the acid, but dissolved with formation of a basic salt in water, and formed a blood red liquid. With an anode of very close-grained gas carbon, and six Smee cells, conduction occurred freely, and the carbon rapidly disintegrated. Anodes composed of fifteen different kinds of carbon of dense woods were tried with a current from ten elements; those made from kingwood, beech, ebony, boxwood, and lignum vitæ were the best. On immersing them in the acid, even without a current, they evolved bubbles (of air?), cracked, and flew to pieces, and on passing a current they broke immediately, some with violence, projecting the fragments and liquid in all directions—even the densest kinds behaved thus. The most resisting was that made from beechwood. With much difficulty, and by the aid of a magnesium light, it was ascertained that the passage of the current was not attended by any increase of bubbles from the carbon. No special odour besides that of the acid could be detected, but the charcoal, when removed from the liquid, emitted a feeble chlorous odour, as well as that of the acid.

With forty Smee elements and an anode of gold the acid scarcely conducted at all; in half an hour the gold was somewhat corroded, and acquired on its edges a few green crystals, which became red by contact with the moisture of the atmosphere. With a palladium anode the acid conducted more freely, but less so than with one of platinum or charcoal. A current from forty Smee elements caused a palladium anode to corrode, and become covered with a thick brittle crust of a dark red-brown colour upon its outer surface and a brighter red beneath. By prolonged action a quantity of this substance was collected on a plate of platinum upon a heated block of iron, and was subsequently investigated.

In each of these experiments the acid was contained in a large platinum cup immersed in a freezing mixture. The cup was provided with a lid of paraffin to exclude moisture, for which the acid has most intense attraction; it was also divided vertically in the middle by a plate of paraffin, which extended to within about half an inch of the bottom of the vessel, in order to prevent evolved hydrogen touching the anode deposit and rapidly reducing it to metal.

(TO BE CONTINUED.)

---

## CURRENT ENERGY.—XII.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 129.)

Professor R. Clausius remarks ("Mech. Wärmetheorie," Vol. II., Absch. XI., p. 337) concerning Sir W. Thomson's papers on thermo-electricity, after falling foul of the "specific heat of electricity," that the latter has not, so far as he is aware, given any explanation of the cause of thermo-electric currents. Now this is a very important remark, showing characteristics on both sides. There is a striking difference in the methods pursued by the two scientists in starting the subject, in laying the foundation for the mathematical development. It is true that Sir W. Thomson abstained from vain speculation and went straight to the point at once. There are reversible heat effects at the junctions of different metals when currents pass across them. There may be (although then unknown) similar effects in the metals themselves. There is no resultant E.M.F. in a circuit of one homogeneous metal, however it may be heated, and however its section may vary. The effects must be subject to the law of conservation of energy, that is, the first law of thermodynamics. They are very probably subject to the second law as well. Now, with these data, develop the laws governing the E.M.F.'s., without unnecessary hypotheses. Such is the method followed in Sir W. Thomson's papers (whatever may have been his private speculations), the truly scientific method in the strictest sense of the word, bearing in mind its derivation, and what science ought to mean—viz., knowledge, and discarding the vague extended meaning it has gradually acquired in the mouths of the unscientific.

On the other hand, Professor Clausius preludes his investigation, which, it may be remarked, has the same object and result, though applied only to the Peltier effect at junctions of different metals, by speculations on the causes of contact force in general, and of the thermo-electric force in particular, using hypotheses which appear based entirely on the materiality of electricity supposed to act directly at a distance on other electricity, and to be attracted differently by different kinds of matter. It is not easy to express these hypotheses in terms of less gross ideas of electricity without at the same time making them become mere ghosts, of no tangibility and of little utility. Such speculations should, in my opinion, be kept entirely apart from, and in particular should not precede, and so apparently form the groundwork of, a mere development of laws not in any way dependent on the hypotheses; so long as the object of inquiry is the laws, not the causes thereof. We shall endeavour, a little later, to put these speculations regarding contact force in a more modern form, by examining how far they are justified by facts, and dismissing the unessential parts. In the meantime, a few remarks on the general nature of explanations, and on the distinctions between the methods followed by the scientific and by the unscientific speculator, whose name is Legion (though usually spelt in other ways) may be useful to many who feel impelled, by natural instincts, to try and explain something.

It is human nature to speculate, and there will be always plenty of scope for speculation until everything is found out, which will not be for some few million years. We want to know the causes of things, why such and such things happen. Well, the first preliminary should be to find the laws of the phenomena. That is work for the scientific man, and usually difficult work, requiring scientific training and reasoning. When laws are established—which implies a very considerable knowledge of the facts, for otherwise the laws may not become evident—we may speculate on their causes. Or, since it would often be very tedious to wait until sufficient facts are known, we may speculate on the causes of phenomena without knowing anything about the laws governing them. Now this may be done by any one. Not that any one can find out a probable explanation of something strange, but any one can speculate. The more imaginative a man is the better for his speculative powers. Also, if he be unscientific, it is not desirable for him to know too much of the facts of the case, because facts are very unaccommodating, and form a great drawback to the free exercise of the speculative faculties.

The proper method for the unscientific speculator is to seize hold of one or two facts, let the imagination run riot, and develop their consequences without any regard to the quantitative relations which may be necessarily involved, and with complete ignoration of the thousands of other facts which might not fit into the hypothesis conveniently. For it is so easy to leave them out. Thus, there have been remarkable exhibitions of the afterglow in various parts of the world lately, and it is natural to speculate on the cause of such unusual occurrences. The influence of suspended particles in scattering and in absorbing light is well-recognised, and it is very possible that suspended matter has something to do with it. Also, there was a great volcanic eruption in Java lately which sent up an immense quantity of dust and smoke, which must take a long time to settle down again. Now let us speculate. It is known, by observations with the unprejudiced electrometer, that the earth is

Digitized by Google

negatively electrified, and being very large, must therefore contain an immense store of negative electricity. This is known to be self-repulsive, and since the law of force is that of the inverse square, when the particles of electricity are very close together, the repulsion is enormous. No wonder, then, that the thin crust of the earth is sometimes unable to withstand the pressure, but breaks down, when, of course, we have earthquakes and volcanic eruptions. In the latter case an immense quantity of the negative electricity is carried up with the dust and smoke, and is repelled to a great height; until, in fact, the force of gravitation on the matter which carries it balances the repulsion of the negative electricity left behind in or on the earth. Then, of course, the self-repulsive action of the electricity causes the smoke to diffuse itself all round the globe, if there be enough of it, and spread out in a great canopy. Evidently the smoke that rises from chimneys must also be negatively electrified, which explains the fact often observed of smoke rising up nearly vertically, and then spreading out horizontally. And many other curious phenomena may be readily explained by the same natural repulsion of the negative electricity.

But in the hands of the philosopher (not meaning metaphysicians who appropriate the title), with a proper attention to facts arranged in correct perspective, and in especial with a due attention to geometrical and quantitative relations in regard to space, time, motion, energy, &c., speculation becomes a very different thing from the above, and may be most usefully employed in forming hypotheses, which, though they may be themselves very improbable, may be provisionally of great utility, not merely to hang the facts together, but, on account of the inquiries they suggest, to serve as stepping stones to a truer theory. Imagination is required no less than before, but it must be guided by strong sense and understanding.

Examples of useful scientific speculation are innumerable. They are usually gifted with importance by being termed theories, thus leading the uninitiated to take them for more than they are worth. Hypothesis would be a better name than theory, because its sound and associations suggest something suppositious and to be received with caution; whilst theory, on the other hand, has also the much more important meaning exampled in Fourier's "Theory of Heat," Maxwell's "Theory of Electricity" (not the vortex hypothesis to be mentioned), or Rayleigh's "Theory of Sound," which have very little to do with speculations, but are mainly rigid developments of established laws. But it would certainly lead to a considerable loss of dignity were an investigator to speak of "my hypothesis" or "my speculations" on, for instance, the cause of magnetism, instead of the usual "my theory." For it is very well recognised that dignity, or the appearance thereof, has a very imposing effect on all save those who take the trouble to look below the surface. Which is why lord mayors are dressed up in robes and chains, and the judges wear horsehair wigs.

As an example of the highest kind of scientific speculation we may mention a "theory" not very generally known, viz., Maxwell's hypothesis of molecular vortices to explain electricity and magnetism. That remarkable genius happily combined in his robust intellect great mathematical gifts, with immense powers of perception and mental realisation of consequences as a whole as well as in detail. Who but a man of the most vivid imagination could, as he did, frame a hypothesis to explain, by pure mechanism (not clockwork) obeying the dynamical laws, electro-statics and kinetics, and electro-magnetism, all in one consistent scheme? Certainly imagination alone could not do it; a preliminary profound study of the facts and of the already formed theories and hypotheses was required, with the exceptional faculty of being able to digest all that learning, to assimilate the essential and reject the unnecessary parts; besides—it being pre-eminently a mathematical subject—the power of applying his mathematical knowledge. Mathematicians are as plentiful as mushrooms, but few have the applicative power. In fact, given the latter, a little mathematics will go a long way, and a knowledge extending no further than simple equations, if well applied, can be of immense utility to the practical electrician.

Regarding this hypothesis of molecular vortices, Maxwell was so modest as not even to give an account of the same in his great work on Electricity and Magnetism, merely referring to some of its results. This is, perhaps, greatly to be regretted. For it would be very useful in its suggestiveness to future electrical students; and, taken merely as a speculation, it appears to me to be of a far more useful kind than the speculations of the great German electricians who go out from the already three-parts extinct idea of the direct action of free electricity on itself at a distance, and develop their hypotheses in electro-dynamics to suit, having to adopt strange devices in order to get rid of the electro-static force as soon as ever the electricity is set moving. For physical theories, nothing can be more inharmonious with the modern spirit of physical science.

Maxwell's hypothesis is exceedingly unlikely to correctly represent the reality; the details are sufficient to show many improbabilities; but it proved that a dynamical explanation of electricity is possible, and that no actions at a distance are required. The final theory of electricity will most probably be strictly in terms of matter and motion, with, however, an intermediate medium of some kind, which cannot be done without. This will, perhaps, be very disagreeable to the imaginative unscientific, to whom dynamics is so odious that they must try and alter the fundamental notions, making, for example, force the square root of energy. As if, by any human possibility, the laws of motion could be capable of adjustment to suit individual eccentricities. They must be taken as they are. Other laws may prevail in other worlds, where spirits have their *habitat*; but in this special world of ours we must abide by whatsoever laws of motion we find working therein, or else receive a fearful punishment.

We are set down in space, to march with time, and have matter in motion everywhere around us. What space and time may be, the metaphysicians may decide, if they can; and, if they cannot, they might as well leave them alone to take care of themselves. It is enough for the scientist that they are—no matter what, and that Nature is not capricious, but orderly. In all speculations established elementary laws should be attended to, theories must be made to fit them, not the reverse, and the object should be to make a science as exact as possible, and bring everything under numerical relations. It may be objected that some branches of knowledge are so heterogeneous in their nature, and cover such an extent of ground, that they can never be brought under the rule of quantitative measurement. Yes, and for that very reason they must always remain speculative, and their theories consist mainly of imperfect generalisations, to be repeatedly altered, affording never-ending material for discussion and argument. Political economy can never be a science in the same sense as Electricity, even if what takes place in electrical phenomena remain for ever unknown. But just in proportion as a branch of knowledge rises from being a heterogenous collection of facts and imperfect laws to being a system, consistent in all its parts, so does it become scientific, and under the rule of exact relations. So long as there is uncertainty as to exactly how much a certain effect amounts to under given circumstances, it cannot be a finished science. Even chemistry, that vast subject with so little coherence, is being made exact, now that chemical affinities are being measured, and the amounts of energy corresponding to the union of definite quantities of matter determined. Under the rule of numbers must all sciences come, to be worthy of the name. A few men may confound mathematics with metaphysics (strange delusion!), and vent their scorn upon the former—sour grapes to them. But it will not do. For them to ignore already established mathematical relations in their speculations is fatal to their accuracy. The mathematicians are very greatly to be thanked. Consider the present science of electricity, with its various units, measuring instruments, and methods. Who have made this possible? The mathematicians. It would be very little use accumulating piles of facts without having the mathematicians to sift them, discover the numerical relations, test various theories with the mathematical touchstone, and gradually turn chaos into system, as they have done in electricity.

Digitized by Google

Now, with regard to explanations, which it is the object of speculations to furnish. Some are more mysterious than the mystery to be explained, in this respect resembling the explanation of some of the Ancients as to how the world was supported, viz., on the back of an elephant, which in its turn stood on a tortoise's back, and goodness knows what the tortoise had to stand on. Such explanations find favour with the unscientific who cannot bear to have no explanation, who would rather worship a false god than none at all. Then there are poetical explanations of natural phenomena. As might be expected, these are *very* bad. The illustrious Göethe's explanation of colour should be a caution to poets to the end of time to keep to their poetry. He borrowed a prism, stuck it to his eye, and looked through it. He did not see Newton's spectrum, but something quite different, and hastily concluded that Newton's theory was all wrong, and set to work to write a book in which the whole thing was properly explained, and Newton's theory demolished. He, in his complete confidence in his theory, astonishing ignorance of the subject, contempt for Newton's theory, and hatred of the methods of the French mathematicians who had developed the laws of polarisation mathematically, displayed many of the characteristics of the unscientific explainer, whilst the complete ignoration of the great poet's theory by the scientists was no less characteristic of them.

That explanation was purely unscientific. But an explanation may be scientific without being real, the invention of fluids to explain electric and magnetic phenomena, for instance. These conceptions were, and are still, useful enough in their way, but we should avoid attaching any more reality to them than they deserve. Let them be servants, not masters. Again, light is popularly explained by the vibrations of a medium called the ether, and I understand Professor Tyndall to go so far as to believe it certain that the particles of ether really *vibrate* transversely to the direction of propagation. But here we should remember that what is known is that the propagation of light through space is a transverse periodic phenomenon of some kind, not that it consists of vibrations of the kind supposed, for many other transverse periodic arrangements may be imagined. A problem, the data of which are very imperfectly known, may have many solutions, instead of but one, and that a certain hypothesis seems to explain is no proof that it furnishes the correct explanation.

Also, it is common to attribute to explanations more virtue than they are entitled to. If we explain the electrification of two conductors by saying that the medium between them is polarised, which it may be, and very likely is, what we do is to electrify all the intermediate particles between the conductors, thus shifting the mystery without in any way explaining in what the polarisation consists. Or if, after Weber, we say that the molecules of iron are themselves magnets, with polarity and orientation, and that they may be rotated by external magnetic influence, so that by the consequent preponderance of molecules pointing their magnetic axes in certain directions rather than in others the iron may be made to show its magnetisation externally, although a very important step is made as regards the probable actual facts of magnetisation, do we thereby explain in any way, or even hint at an explanation of the Cause of Magnetism? Not in the least. The nature of the magnetism of a molecule is just as great a mystery as that of a collection of molecules forming a connected mass.

What, then, is a real explanation? Obviously nothing can be wholly explained, for that would require infinite discernment. But complexity may be resolved into simplicity, for one thing. This process of disentanglement, whereby by pure reasoning, without hypothesis, or with mere working hypotheses that may be thrown off, we may put a complex set of phenomena in order, as it were, and exhibit their mutual relations, may be all the explanation we can get, *i.e.*, the explanation of complex cases in terms of simpler ones of the same type. But, for another thing, some phenomena are so familiar to us and so universal that, although equally mysterious in themselves, they seem to less need explaining; so, taking them for granted, we seem to obtain a real explanation if we can resolve obscure facts into the familiar ones. This may be much more than the mere disentanglement above mentioned, being a change of type as well.

That remarkable triumph of hard-headed men, the kinetic theory of gases, is a case in point. The properties of gases are explained, and very completely up to a certain point, dynamically, with approximate estimates of the size and mass of molecules, on the ridiculously-simple hypothesis that a gas consists of an immense number of small particles in motion, left entirely to themselves and the operation of the ordinary laws of motion and of collision of elastic spheres. This is something deserving the name of explanation, and is a real gain of knowledge. To matter and motion must electricity come before it can be said to be explained, though certainly it will be not quite so simple an affair as the above, the question being complicated with the ether as well.

After that, there is the nature of molecules, and of matter in general. And even if we resolve all matter into one kind, that one kind will need explaining. And so on, for ever and ever deeper down into the pit at whose bottom truth lies, without ever reaching it. For the pit is bottomless.

---

## A HISTORY OF ELECTRIC TELEGRAPHY TO THE YEAR 1837.

BY J. J. FAHIE, MEMB. SOC. TEL. ENGS. AND ELECS.*

NOTE.—Being anxious to make his History as complete as possible, the Author will be grateful to his readers for any information, no matter how small, in relation to the subjects treated of in these pages.

(CONTINUED FROM PAGE 189.)

### CHAPTER VI.—ELECTRO-MAGNETISM AND MAGNETO-ELECTRICITY.

#### HISTORY IN RELATION TO TELEGRAPHY.

In November, 1825, a great advance was made on Arago's experiment of magnetising soft iron, by the invention of the electro-magnet—an instrument which, in one form or another, has become the basis of nearly every system of electric telegraphy. We owe this most important contrivance to Sturgeon, a well-known electrician of Woolwich, who had worked in his earlier days at the cobbler's last,† as Franklin had done at the

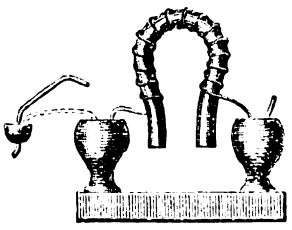

FIG. 1.

printing stick, and Faraday at bookbinding. Fig. 1 shows the earliest form of the instrument—a piece of stout iron wire, bent into the form of a horse-shoe, coated with an insulating varnish, and then bound round loosely with bare copper wire, the turns (of which there were sixteen) being, of course, separated from each other. This electro-magnet, when excited by a single voltaic pair of large (130 square inches) surface, was capable of supporting a weight of nine pounds, a wonderful performance in those days. (*Transactions Society of Arts*, 1825, Vol. 43, pp. 38—52.)

Some of the further steps in the perfection of the electro-magnet as used in telegraphy were made by Professor Henry in America, between the years 1828 and 1831, and it will be interesting to retrace them here, if only to see how little learned professors, fifty years ago, understood the conditions underlying the conversion of voltaic into magnetic force, and consequently how much groping in the dark, and stumbling to conclusions, where now Ohm's celebrated law makes everything so clear.

Henry was led to his first improvements in electro-magnets by a study of Schweigger's galvanometer, which resulted in the idea that a much nearer approximation to the requirements of

* The author reserves all rights of translation.

† He was apprenticed to a shoemaker, and disliking the employment, at the age of nineteen, entered the Westmoreland Militia, and two years later enlisted in the Royal Artillery. While in this corps he devoted his leisure to scientific studies, and made himself familiar with all the great facts of electricity and magnetism, which were then opening on the world. His subsequent career has created for him an undying name in the annals of electricity.

Ampère's theory could be attained by insulating the conducting wire itself, instead of the rod to be magnetised, and by covering the whole surface of the iron with a series of coils in close contact.

In June, 1828, he exhibited at the Albany Institute of New York, of which he was then professor, his electro-magnet, constructed on this principle. It consisted of a piece of soft iron, bent in the form of a horse-shoe, and closely wound with silk-covered copper wire, one-thirtieth of an inch in diameter. In this way he was able to employ a much larger number of convolutions, while each turn was more nearly at right angles with the magnetic axis of the bar. The lifting power of this magnet was, conformably to Henry's anticipations, much greater, *ceteris paribus*, than that of Sturgeon.

In March, 1829, he exhibited, at the same place, a somewhat larger magnet of the same character. A round piece of iron, about one quarter inch diameter, was bent into the usual horse-shoe form, and tightly wound with thirty-five feet of silk-covered wire, in about four hundred turns, with silk ribbon between. A pair of small battery plates, which could be dipped into a tumbler of dilute acid, were soldered, one to each end of the wire, and the whole mounted on a stand. With this small battery the magnet could be much more powerfully excited than another of the same sized core, wound according to the method of Sturgeon and excited by a battery of twenty-eight plates of copper and zinc, each plate eight inches square (*Smithsonian Report*, 1878, p. 282).

"In the arrangement," says Henry, "of Arago and Sturgeon, the several turns of wire were not precisely at right angles to the axis of the rod, as they should be to produce the effect required by the theory, but slightly oblique, and, therefore, each tended to develop a separate magnetism not coincident with the axis of the bar. But in winding the wire over itself, the obliquity of the several turns compensated each other, and the resultant action was at right angles to the bar. The arrangement, then, introduced by myself was superior to those of Arago and Sturgeon, first, in the greater multiplicity of turns of wire, and second, in the better application of these turns to the development of magnetism.*

"The maximum effect, however, with this arrangement and a single battery was not yet obtained. After a certain length of wire had been coiled upon the iron, the power diminished with a further increase of the number of turns. This was due to the increased resistance which the longer wire offered to the conduction of electricity. Two methods of improvement, therefore, suggested themselves. The first consisted, not in increasing the length of the coil, but in using a number of separate coils on the same piece of iron. By this arrangement the resistance to the conduction of the electricity was diminished, and a greater quantity made to circulate around the iron from the same battery. The second method of producing a similar result consisted in increasing the number of elements of the battery, or, in other words, the projectile force of the electricity, which enabled it to pass through an increased number of turns of wire, and thus to develop the maximum power of the iron." (*Smithsonian Report*, for 1857, p. 102.)

Employing a horse-shoe, formed from a cylindrical bar of iron, half an inch in diameter, and about ten inches long, and wound with thirty feet of fine copper wire, he found that, with a current from only two-and-a-half square inches of zinc, the magnet held 14lb.† Winding upon its arms a second wire of the same length (30 feet) whose ends were similarly joined to the same galvanic pair, the magnet lifted 28lb. On these results Henry remarks:—

"These experiments conclusively proved that a great development of magnetism could be effected by a very small galvanic pair, and also that the power of the coil was materially increased by multiplying the number of wires, without increasing the length of each. The multiplication of the wires increases the power in two ways: first, by conducting a greater quantity of galvanism, and secondly, by giving it a more proper direction; for since the action of a galvanic current is directly at right angles to the axis of a magnetic needle, by using several shorter wires we can wind one on each inch of the length of the bar to be magnetised, so that the magnetism of each inch will be developed by a separate wire. In this way the action of each particular coil becomes directed very nearly at right angles to the axis of the bar, and consequently the effect is the greatest possible. This principle is of much greater importance when large bars are used. The advantage of a greater conducting power from using several wires might, in a less degree, be obtained by substituting for them one large wire of equal sectional area; but in this case the obliquity of the spiral would be much greater, and consequently the magnetic action less."*

In the following year, 1830, Henry pressed forward his researches to still higher results, assisted by his friend, Dr. Philip Ten-Eyck. "A bar of soft iron, 2in. square, and 20in. long, was bent into the form of a horse-shoe 9½in. high (the sharp edges of the bar were first a little rounded by the hammer); it weighed 21lb. A piece of iron from the same bar, weighing 7lb., was filed perfectly flat on one surface for an armature, or lifter. The extremities of the legs of the horse-shoe were also truly ground to the surface of the armature. Around this horse-shoe 540ft. of copper bell-wire were wound in nine coils of 60ft. each; these coils were not continued around the whole length of the bar, but each strand of wire (according to the principle before mentioned) occupied about 2in., and was coiled several times backward and forward over itself. The several ends of the wires were left projecting, and all numbered, so that the first and the last end of each strand might be readily distinguished. In this manner we formed an experimental magnet on a large scale, with which several combinations of wire could be made by merely uniting the different projecting ends. Thus, if the second end of the first wire be soldered to the first end of the second wire, and so on through all the series, the whole will form a continued coil of one long wire. By a different arrangement the whole may be formed into a double coil of half the length, or into a triple coil of one-third the length, and so on. The horse-shoe was suspended in a strong rectangular frame of wood, three feet nine inches high, and twenty inches wide."

The accompanying figure, which we copy from the *Scientific American*, December 11, 1880, is an exact representation of this instrument, which is at present preserved in the College of New Jersey.

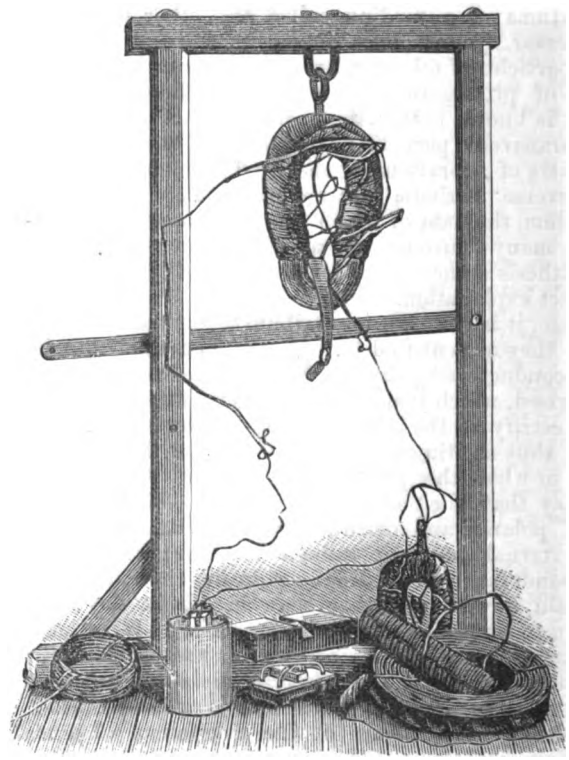

FIG. 2.†

Two of the wires, one from each leg, being soldered together so as to form a single circuit of one hundred and twenty feet, gave a lifting power of sixty pounds. The same two wires separately connected with the battery so as to form a double circuit of sixty feet each, produced a lifting power of two hundred pounds; and four wires used in the same way supported as much as five hundred pounds. Six wires united in three pairs, so as to form three circuits of one hundred and eighty feet each, gave

* "When this conception," said Henry, "came into my brain, I was so pleased with it that I could not help rising to my feet and giving it my hearty approbation." It was his first discovery. See Professor Mayer's Eulogy of Henry, before the American Association for the Advancement of Science, 1880.

† It must not be forgotten that at the time when this experimental magnet was made, the strongest electro-magnet in Europe was that of Sturgeon above mentioned, and then considered a prodigy.

* Silliman's *Am. Journal of Science*, Jan. 1831, vol. xix., p. 402.

† The coil at the right of the engraving represents the original silk-covered ribbon wire used by Henry in his celebrated experiments on induction. In the middle of the foreground is one of his pole-changers, which could also be used as a circuit breaker. He was accustomed to delight himself and his classes with this by making and breaking the current so quickly that a twenty-eight lb. armature could not fall off, but was freed and attracted with a sharp snap.

Digitized by Google

a lifting power of only two hundred and ninety pounds; while the same wires, when separately connected, as six parallel circuits, supported five hundred and seventy pounds, or nearly double. When all the nine wires were joined up in parallel circuits with the battery, a lifting power of six hundred and fifty pounds was produced.*

In all these experiments a small single pair was used, consisting of two concentric copper cylinders, with a zinc one between, the active surface of which (on both sides) amounted to only two-fifths of a square foot. The exciting liquid consisted of half a pint of dilute sulphuric acid. A maximum portative force of 750lbs. was obtained from a zinc-copper pair of 144 inches of active surface, all nine coils being joined in multiple arc. (Silliman's *Journal*, January, 1831.)†

The only European physicist, who, up to this time, 1830, had obtained any results even approaching these, was Gerard Moll, professor of natural philosophy in the University of Utrecht, who having seen in London, in 1828, an electro-magnet of Sturgeon which could support nine pounds, determined to try the effects of a larger galvanic apparatus. Having formed a horse-shoe, twelve and a half inches high, and two and a quarter inches diameter, he surrounded it with twenty-six feet of insulated copper wire, one eighth of an inch thick, in a close coil of forty-four turns. The weight of the whole was about twenty-six pounds. With a current from a pair of eleven square feet of active (zinc) surface, this magnet sustained 154lbs. This result was considered astonishing in Europe,‡ yet Henry's horse-shoe, less in size and weight, supported nearly five times this load, with one-eleventh of Moll's battery power.

After finding that the maximum attractive power was obtained by his artifice of multiple coils, Henry proceeded to experiment with electro-magnets formed of one long coil; and soon he was rewarded by a new discovery, namely, that, though multiple coils yielded the greatest attractive power close to the battery, one long continuous coil permitted a weaker attractive power to be exercised at a great distance, or through a great length of intervening wire.

Employing his earlier and smaller magnet of 1829, formed of a quarter-inch rod, and wound with eight feet of insulated copper wire; he tried the effects of different battery powers, of different lengths of external wire, and of different lengths of coil. Excited with a single pair of zinc and copper, having fifty-six square inches of active surface, the magnet, alone in the circuit, sustained four and a half pounds. With five hundred feet of copper wire, ·045 inch diameter, interposed between battery and magnet, the weight supported was only two ounces, or thirty-six times less than in the first case. With one thousand feet of wire interposed, the lifting power of the magnet was only half an ounce.

Using now a trough battery of twenty-five pairs, the magnet in direct connection (which, with a single pair, had supported four and a half pounds) lifted but seven ounces; while with the thousand feet of wire interposed as before it sustained *eight* ounces.

"From this experiment," says Henry,§ "it appears that the current from a galvanic *trough* is capable of producing greater magnetic effect on soft iron after traversing more than one-fifth of a mile of intervening wire than when it passes only through the wire surrounding the magnet. It is possible that the different states of the trough with respect to dryness may have exerted some influence on this remarkable result; but that the effect of a current from a trough, if not increased, is but slightly diminished in passing through a long wire is certain. * * * From these experiments it is evident that, in forming the coil, we may either use one very long wire, or several short ones, as circumstances may require. In the first case, our galvanic combination must consist of a number of plates, so as to give 'projectile' force; in the second, it must be formed of a single pair."

Henry was thus the first to practically work out the different functions of two entirely different kinds of electro-magnet; the one, of numerous short coils, which he called the *quantity* magnet, and the other, of one very long coil, which he designated the *intensity* magnet. The former and more powerful, although little affected by a battery of many plates, was fully charged by a single pair; while the latter and feebler, which was but slightly affected by a single pair, was not only greatly excited by a battery of numerous elements, but was capable of receiving this excitation from a distant source.

In fact, Henry experimentally established the important principle that there must be a proportion between the (internal) resistance of the battery and the (external) resistance of the rest of the circuit; and its corollary, that, by combining an *intensity* battery, of many small pairs, with an *intensity* magnet, of a long fine wire, a very long intervening conductor can be employed without sensible diminution of the effect—a fact which lies at the root of every system of electro-magnetic telegraphy.*

In the course of these pages we have had abundant evidence of the fact that motion could produce electricity, and electricity motion. Dessaignes showed us how difference of temperature, or heat, could produce electricity;† and Peltier gave us the strict converse of this in the conversion of electricity into heat, including both its relations—hot and cold; again we have seen how the nervous force in certain fishes could produce electricity, the converse of which was long and vainly sought after by Galvani and his disciples.

When, therefore, Oersted discovered the property of electricity to deflect a magnetic needle, and Arago its corollary—the magnetising power of the current, the conviction became strong that magnetism must be able in some way to produce electricity.

The credit of completely establishing this connection fell to the lot of our distinguished countryman, Michael Faraday. In his brilliant series of "Experimental Researches" commenced in 1831 he says:—"Certain effects of the induction of electrical currents have already been recognised and described; as those of magnetisation, Ampère's experiments of bringing a copper disc near to a flat spiral, his repetition with electro-magnets of Arago's extraordinary experiments, and perhaps a few others. Still, it appeared unlikely that these could be all the effects which induction by currents could produce. * * *

"These considerations, with their consequence, the hope of obtaining electricity from ordinary magnetism, have stimulated me at various times to investigate experimentally the inductive effect of electric currents."

Faraday thus describes his first successful experiment.—"203 feet of copper wire in one length were coiled round a large block of wood; other 203 feet of similar wire were interposed as a spiral between the turns of the first coil, and metallic contact everywhere prevented by twine. One of these helices was connected with a galvanometer, and the other with a battery of 100 pairs. * * * When the contact was made, there was a sudden and very slight effect at the galvanometer, and there was also a similar slight effect when the contact with the battery was broken. But whilst the current continued to flow through the one helix no galvanometrical appearances nor any effect like induction upon the other helix could be perceived."

Faraday produced the same effects in another way. Several feet of copper wire were stretched in wide zigzag forms, representing the letter W, on the surface of a broad board; a second wire was stretched in precisely similar forms on a second board, so that when brought near the first, the wires should everywhere touch, except that a sheet of thick paper was interposed. One of these wires was connected with a galvanometer and the other with a voltaic battery. The first wire was then moved towards the second, and as it approached the needle was deflected. Being then removed, the needle was deflected in the opposite direction. As the wires approximated the induced current was in the *contrary* direction to the inducing current; and as they receded the induced current was in the *same* direction as the inducing current.

* Henry was called to the chair of Natural Philosophy in the College of New Jersey, at Princeton, in 1832, and there he made two larger magnets or use in his investigations. One weighing 59½ pounds, and capable of sustaining 2,063 pounds, is now in the cabinet of Yale College. The other, made in 1833, weighed 100 pounds, and could support 3,500 pounds. It was many years before any magnet approaching this in power was constructed.

† With a pair of plates, exposing exactly one square inch surface, the same arrangement of the coils could sustain a weight of 85 pounds!

‡ Brewster's *Edinburgh Journal of Science*, October, 1830, p. 214.

§ Silliman's *Journal*, January, 1831, p. 403. Here is an instance of the stumbling to conclusions of which we have spoken previously.

* In 1827, Georg Simon Ohm, professor of physics at Munich, published his celebrated formulæ; but for many years they failed to attract attention, and were no doubt unknown to Henry in 1830, as they were to Wheatstone in 1837. Numerous researches have, since Henry's time, been made with the view of determining in a rigorous manner the conditions necessary for obtaining the greatest electro-magnetic force. For these see Ganot's "Physics," London, 1881, p. 783; Noad's "Text Book of Electricity," London, 1879, p. 285; Du Moncel's "Elements of Construction for Electro-Magnets, London, 1883, *passim*; and the back volumes of *The Electrician*, for papers by Schwendler, Heaviside, &c.

† In 1815, or six years before Seebeck, who is always credited with the observation. See Bostock's "History of Galvanism," London, 1818, p. 101. Many observations bearing on *thermo-electricity* had been made even long before Dessaignes. Passing by that of Theophrastus, 321 B.C., that tourmaline could be electrified by friction, as irrelevant, since he does not appear to have had any idea that the effect might be due to heat produced by the friction, we find that, in the year 1707, the thermo-electric properties of tourmaline were unmistakably pointed out by a German author, "J. G. S.," in his "Curious Speculations During Sleepless Nights." In 1759, Æpinus called attention to the same phenomena, and pointed out that electricity of opposite kinds was developed at opposite ends of the crystal. In 1760, Canton observed the same properties in the topaz; and between 1789 and 1791, Haüy showed the thermo-electric properties of various other substances, as mesotype, prehnite, Iceland spar, and boracite. (Priestley's "Hist. of Elec.," 1767, pp. 314—26).

## REVIEW OF THE YEAR 1883.

(CONTINUED FROM PAGE 186.)

CABLE WORK.—Before continuing our remarks upon electric light operations, we shall introduce and deal with that most important branch of electrical work—submarine telegraphy. We have always maintained, and we do not know that our view has been disputed, that cable work demands higher qualities than any other branch of electrical engineering. We have referred to the making of history. A correspondent this week shows that however well meaning a writer may be, however conversant with the subject, it is almost impossible to attempt to detail history without committing a more or less obvious error. Now, the history of submarine telegraphy wants writing. The promoters of the work—at least, many of them—are still living; those who have carried on and are continuing the work are also, for the most part, among us. If ever its authentic history is to be written, no time could be better than the present. The narrative of one would be corroborated by the narrative of others, and so far as fallible mortals are concerned, we could hand down to posterity the true history of one of the greatest achievements the world ever saw. It is all very well to argue that submarine work is but an extension of land telegraphy. That may be good enough for the marines, but all those who have a smattering of electrical knowledge know better. They know that new laws were discovered, new difficulties encountered, new apparatus invented, altogether distinct from the laws, difficulties, and apparatus in connection with land work. The highest electrical talent that the world could produce has been imported into cable work. In every branch we have those who stand in the very front rank of scientific men. The reputation of those whom we are delighted to honour has been principally made in connection with submarine work. There is one thing we might suggest, and that is, that any friend should send to us his reminiscences of the early days, also any pamphlets, instructions, or books that contain references to the time and work mentioned.

It has always seemed to us, however, that while successes in manufacturing, laying, and working a long cable were great achievements, a greater was in the picking up in deep water of an old cable, splicing and returning it to its oozy bed. We have recorded several instances where this has been done in water over a thousand fathoms deep, and during the past year the "Scotia," belonging to the Telegraph Construction and Maintenance Company, and the "Volta," belonging to the Eastern Company, have been successful in such work. Few readers of *The Electrician* fully realise the difficulty of picking up a cable lying from 6,000 to 12,000ft. below the surface. The fabled needle in a truss of hay is a far easier find. The bottom of the sea has not the smooth configuration of a billiard table, nor are the grapnels the most delicate of instruments; but, nevertheless, the use of the grapnels and the success obtained in repairing deep sea cables have become matters of history. The most recent work is that of the "Scotia," which left Greenwich on November 1, 1883, to repair the Brazilian Submarine Company's cable between St. Vincent and Pernambuco. This fine vessel was under the command of Captain Cato. The cable was faulty in deep water about midway between the two places. The ship arrived on the cable ground on November 16, and after great difficulties, owing to weather and water, grappled the cable, and completed the repairs by December 5. The depth over which grappling took place varied from 1,000 to 2,000 fathoms. The success of the "Volta" upon the Porthcurnow-Lisbon cable earlier in the year in 1,900 fathoms water was recorded in our columns. Another repair by the Eastern Company's ship "John Pender" was satisfactorily accomplished in 500 fathoms upon the Porthcurnow-Vigo cable. Another repair worthy of note was one on the Madras-Singapore cable of the Eastern Extension Company, which was done in the middle of the monsoon. This repair was indeed satisfactory, and may be looked upon as another success of science, inasmuch as such repairs must be begun and finished during a lull in the weather. Nay, the vessel must leave shelter and complete her work during the lull. Great watchfulness, great accuracy, celerity, and confidence are necessary in such cases. The 1871 Banjoewanjie-Port Darwin cable of the Eastern Extension Company has also been repaired during the year. This repair was a difficult one, owing to the weather and the rough nature of the bottom. Such successes as we have here indicated must add greatly to the confidence of share-

Digitized by Google

holders in these vast undertakings, and must tend to make investment in cable shares much less of a speculation, and far more of the nature of "safe" investments, than was formerly thought to be possible. This in itself must redound to the credit of those who have consistently and persistently worked for the benefit of submarine telegraphy.

The total number of miles of new cable laid during the year does not equal that laid during some previous years, but sums up to a very respectable total, and when we consider that a good deal of work is in hand that will augment the total of 1884 there is no reason to be disheartened. Thus the Silvertown Company is busy completing the laying of the Cadiz-Senegal cable. We have recorded the start of this expedition, the excellent work done by it in the matter of soundings, and the completion of a large section of the work, and we hope soon to have to record the final success of the whole. Messrs. Siemens are said to be busy over new Atlantic cables. Speculators in cables imagine the Atlantic a modern Golconda, or rather we should say they imagine the Anglo-American Company to be a bull existing only to be baited. There is nothing we should like to see better than these speculators getting a regular burning of their fingers. But to resume. The Eastern Telegraph Company has laid a triplicate Suez-Aden cable some 1,500 miles in length. This cable was manufactured and laid by the Telegraph Construction and Maintenance Company, and is of the most approved type, the whole being covered with brass tape. The ships employed in this work were the "Seine" and "Kangaroo." The same company has also made and laid some 965 miles of cable for the Eastern Extension Company. This cable is known as the Hong-Kong-Shanghai cable. One section is laid from Hong-Kong to Fouchow, another from Fouchow to Shanghai. Of this cable some 95 miles are of specially heavy type for laying up river. The "Scotia" was employed on this work. The Telegraph Construction and Maintenance Company also manufactured and laid some 1,369 miles of cable for the Great Northern Telegraph Company. The "Scotia" and "Seine" were the vessels employed, and the cable was laid in sections from Vladivostock to Nagasaki, thence to Gutzlaff, from which place a three-core river cable of 65 miles length was laid up the Yang-tse-Kiang to Woosung. In addition to the work done, the same company has made and sent out cable to connect Shanghai with Hué and Tonquin for the Eastern Extension Company, under a concession from the French Government, dated December 23, 1883, and it is intended to connect Tonquin with Hong-Kong, using for this purpose cable from the stock at Singapore. The extent of cable communication with the East will be better understood when we say that the length of cable and connections belonging to various companies is between 38,000 and 39,000 miles. Thus:—

| | Miles. | Land lines. |
|---|---|---|
| Eastern Telegraph Co.'s cables.. | 18,225 | 2,744 |
| Eastern Extension Co.'s „ | 13,522 | 24 |
| Eastern and South African „ | 3,863 | 6½ |
| Black Sea „ | 351 | 27 |
| Totals | 35,961 | 2,801½ |

giving a grand total of some 38,763 miles. This total includes that to be laid by the ships now in the East. When we add to this total the Western lines to America, and on the west coast of America, we find that there is in working order some 60,000 or 70,000 miles of cable. We have referred to the action of speculators with regard to Atlantic cables, hence do not refer to them in the following table, which shows the increase in value of cable property during the last five years:—

| Company. | Jan. 4, 1879. | Jan. 5, 1884. |
|---|---|---|
| Brazilian | 6⅜ | 10 |
| Cuba | 8¼ | 10¾ |
| „ Pref. | 15 | 17 |
| Direct Spanish | 1¾ | 4½ |
| „ „ Pref. | 9⅛ | 15 |
| Eastern | 7¼ | 10¾ |
| „ 6 per Cent. Pref. | 10⅞ | 13 |
| Eastern Extension | 7 1/16 | 11¼ |
| Great Northern | 7⅝ | 12⅞ |
| Indo-European | 19 | 31½ |
| Western and Brazilian | 2½ | 5⅛ |

The current quotations of the Mediterranean Extension, of Reuter's, of the Submarine, of the West India and Panama, are lower now than five years since. The tendency is, as will be seen, for cable property to improve. These facts and figures are the best possible proof of the admirable management which holds with the great cable companies.

TELEPHONY.—The progress made in extending the telephone during 1883 has been decidedly slow. Let us hope it is sure. In London this progress has been, perhaps, slower and less sure than in some of our larger provincial towns. People cannot wait half-an-hour to get an answer from the exchange, nor do they like to hear two or three voices in addition to that of the person they are talking to, as conversation in such cases is difficult. And experiences such as these are by no means exceptional in London. The telephone is one of the most useful and at the same time one of the most delicate instruments of modern times, and requires proportionate care at the hands of those who fit it up. When the work of running telephone wires and fitting up transmitters and receivers is entrusted to the careless or ignorant, the result is too frequently that the telephone is voted a nuisance and discarded. "'Tis true, 'tis pity, pity 'tis 'tis true." Then, again, the annual subscriptions exacted for its use are far too high, and greatly retard extension. A lower tariff would we feel assured have stimulated a greater demand. At the end of last year both America and France were far ahead of us in their use of the telephone, and the end of 1883 finds the gap still wider. We are fain to confess that we think the policy adopted by those in whose hands the telephone has fallen here is entirely to blame for this state of affairs. It has been a shortsighted, bullying, catchpenny policy, and the result has been that the telephone has suffered and the public have held aloof from it.

A vast amount of money was spent in the Law Courts in 1882 by the United Telephone Company in maintaining their patents against all comers, and this sum has been added to during 1883. In the early part of the year Messrs. Harrison, Cox-Walker, and Co.'s appeal against Mr. Justice Fry's decision relating to the Bell receiver was decided; and three separate judgments were delivered by as many judges in favour of the United Company. Then in May this company brought an action against the Long-Distance Telephone Company, as owners of the Hopkins patents, for infringing the Bell and Edison patents, and sought an injunction restraining the sale or use of the Hopkins instruments until the trial of the action. So far as we know this case has never been finally settled, a compromise being come to between the two companies by which the Long-Distance Company agreed to submit to an interim injunction without prejudice to the question of the action, should it be tried. About the same time the London and Globe Telephone Company and the United Company fell foul of one another in the matter of

Digitized by Google

wires, and all kinds of charges and counter-charges as to cutting and tying up wires were made by the *employés* of either company against one another. This case alternated between the police courts and the Court of Chancery, the only persons ultimately benefited being the lawyers. Indeed it seems as if these latter gentlemen will continue to be benefited in the coming year as in the past, for infringements of patents and overhead wires are fruitful sources of litigation.

A very pretty quarrel of a different class to those above mentioned was waged in our pages during the past year on the subject of Reiss's claims to be considered the inventor of the telephone, Professor Silvanus Thompson coming forward as a warm and enthusiastic advocate of his case. This literary warfare has now transferred itself to the American papers, but the arguments used do not appear to have much freshness about them, and the matter has, we think, been pretty well thrashed out in these columns.

To telephone over long distances and obtain good results is the dream of telephone engineers and inventors. In March last the world was startled by an announcement to the effect that 1,000 miles had been telephoned over in America with ease, and that New York and Chicago were within speaking distance. As we pointed out at the time this was not such a wonderful feat, given good conditions of weather and line, and had been already beaten in Australia. It is scarcely likely to be accomplished in our foggy island, even if the distance were halved, so that the further development of long distance telephony may be left to our cousins without a pang of jealousy. That the telephone will, however, be eventually used as a means of communication between our large towns we firmly believe.

A great many patents have been taken out during the year for various improvements in telephones, but little has been heard of them outside the Patent Office. The St. George telephone was exhibited in July last, and has been talked about in various daily papers since, but we very much doubt whether it is likely to be adopted for practical work. M. van Rysselberghe has been active in perfecting his system, and several trials of it have been made in Belgium, with considerable success. The latest news from Brussels was to the effect that a concession had been granted by the Government to the owners of M. van Rysselberghe's patents, giving them the use of the Belgian telegraph lines for the working of this system. A Belgian paper, *La Flandre Liberale*, has used this means of communication between its Ghent and Brussels offices for several months. Successful trials have also been carried out in Holland.

Overhead telephone wires have increased in London during the past year until the outcry against them has become universal. Not only are single wires strung at every conceivable angle across our streets, but heavy cables are now to be seen crossing and re-crossing our busiest thoroughfares, dangling in mid-air in all their hideous ugliness. Unfortunately, they are not only ugly—if they were but this, we might tolerate them—they are also an imminent source of danger. Mr. Preece notwithstanding, we are of opinion that these wires must go underground. Why did not those concerned seize upon the opportunity offered by the completion of the underground railway between Aldgate and the Mansion House to construct a subway for wires? They cannot imagine that because they are allowed to go on in the present easy fashion that this state of affairs will always be tolerated. London, like New York, Philadelphia, and Chicago will wake to the fact that all wires must be buried, and then there will be considerable repining in certain quarters that this eventuality was not looked in the face from the first. As our readers know, a committee has been formed in New York to consider the best plan of putting all wires underground, and though the difficulties are very great, there is no reason why they should be insurmountable.

Practical telephony in all its details has been graphically explained to our readers during the latter half of this year in a series of articles written specially for us by a gentleman of great practical experience. We hope, and believe, that the series proved useful. In the present volume we are dealing in a somewhat similar way with the French telephonic system, which differs in certain details from that adopted in this country.

No application of the telephone has been made during 1883 that could be described as new, but there are many who believe that its use may be very greatly extended, and are daily occupied in experiments in different directions. Possibly 1884 may witness the publication of the results of these researches.

In reviewing the actual work accomplished during the past twelve months we cannot do better than begin with the Post Office, of whose system we have more than once expressed ourselves in terms of high praise, which we have seen no reason to modify. As all the world knows, legal acumen has decided that telephone and telegraph are synonymous; consequently it is but right that we should place telephonic and telegraphic work side by side in this article, so far as the Post Office is concerned.

Post Office Telegraphic and Telephonic Service.—In 1882 the construction of a ship specially adapted for the requirements of this department was commenced. The vessel was completed in the autumn of 1883, has been named the "Monarch," and is at the present time in the Thames, being fitted up with cable machinery. As to the "Monarch's" capabilities and special points of construction something may be said at a future date. To allow her to be brought alongside the Submarine Depôt at Woolwich a special berth had to be dredged and moorings fixed, the latter being carried out under the immediate direction of the Thames Conservancy.

During the past year the communication between Great Britain and Ireland has been improved by the laying of an additional cable between Fishguard, in Pembrokeshire, and Blackwater, in Wexford, sixty odd miles in length. To connect this cable of four wires, additional land wires of a corresponding number were required from London to Fishguard and from Blackwater to the towns served in Ireland. The total number of cross channel wires available between the two countries was by this addition increased to twenty-four. Repairs were made upon the Channel Islands cable, the Isle of Man cable, the Holyhead-Howth cable, and upon smaller cables, such as the Granton-Burntisland, the Hurst Castle-Keyhaven, and that across the River Tees.

Numerous extensions of the telegraph were made to places which had not previously been served, but which had either developed into sufficient importance or which were opened under guarantee. In connection with the meteorological station recently established on Ben Nevis, a telegraphic wire has been put down on behalf of the Scottish Meteorological Society between Ben Nevis and Fort William. Owing to the exposed position, it was deemed desirable to put the wire underground for the greater part of the distance.

A new wire was specially erected for the Eastern Telegraph Company, as also a pneumatic tube between that company's London office and the Central Telegraph Station.

During the construction of the Forth Bridge the contractors have found it to their advantage to have telegraphic

Digitized by Google

communication, and for that purpose the department put down a cable across the Forth, between North and South Queensferry.

The past year has not been particularly destructive to the telegraphs, but a heavy gale and snowstorm in the spring seriously interfered with the system in Ireland, and in December an unprecedented gale did severe damage in several parts of England, the telegraph plant suffering very much from fallen trees and signal posts.

At the Vienna Exhibition, held between June and October, the Post Office exhibited all the forms of apparatus at present in use, and also sent over its interesting historical collection of apparatus.

That portion of the department's system which was underground in 1882 has been materially extended during the past year.

The London pneumatic tube system has been increased by extensions to Queen Victoria-street, Seething-lane, &c., and in one or two provincial towns similar extensions have been made. An additional engine of 50 horse-power was brought into use in the early part of the year for the London pneumatic tube service, which is rapidly approaching thirty miles in length.

To provide for the increasing number of telegraph instruments and operators an additional story to the central office has been in hand, and much progress has been made with it.

The electric light has continued to give satisfaction in the Glasgow office, and the female telegraphists' room at Manchester was lighted by incandescent lamps just before the termination of the year.

Numerous inventions and notions have been introduced to the department during the year, some suggesting the encasement of wooden poles in earthenware or waterproof paper for their preservation; others for the placing of wires underground, or for the employment of modified forms of insulators or apparatus, and processes for covering wire for underground purposes, but few were found to possess the germs of practicability.

The telephone exchanges of the department at Plymouth, Middlesbrough, Newcastle-on-Tyne, Hull, Sunderland, between Liverpool and Manchester, Newcastle and Sunderland, Cardiff and Newport, Cardiff and Swansea, West Hartlepool, Cork, Waterford, Falmouth, and Leicester have received many additional subscribers; while numerous trunk lines have been erected by the department for licensed telephone companies.

Improvements for the better working of the system have been introduced by modifications of the sounder instrument the alteration of fast repeaters so that they may be used either duplex or single, at will. Spark condensers have been introduced to prevent sparking at the contact points of fast repeaters. The electro-magnetic arrangement of the Wheatstone receiver has been improved so as to increase its working speed from 200 to 300 words a minute; the mechanical details of the perforator used in connection with the Wheatstone instrument have been simplified; a new form of key has been brought into use on double current circuits worked from universal batteries; "reversing" and "increment" keys for quadruplex circuits have been introduced, whereby "pole reversers" and "single current transmitters" become unnecessary; a new form of non-polarised telephone indicator has been devised, and the whole system of telephone working vastly improved, so as to secure promptitude and attention; the despatch of carriers through pneumatic tubes has been facilitated by an improvement in the sluice valve; improvements have been made in aerial cables by which induction has been diminished, and their conducting capacity increased; standard gauges and ratios between conductors and insulators of covered wires have been adopted, and many improvements have been made in various parts of apparatus, such as rheostats, trembler bells, and terminal indicators for pneumatic tubes. A modification of the sending valve of pneumatic tubes has been introduced, by which the previous possibility of accident to the fingers of an attendant from careless manipulation of the slide while inserting a carrier has been removed. After several years' trial of copper wire for open lines it has been decided to extend its employment on a large scale.

But perhaps the item of greatest importance in connection with the Postal Telegraphs, during the year, was the decision of the House of Commons to adopt a reduced tariff for inland telegrams. That decision having been come to, it was necessary for the department to consider what the effect would be as regarded a probable increase of traffic, and therefore what increased facilities would be required to cope with that increase with the efficiency it had always endeavoured to attain. The result of deliberation was that additional pneumatic tubes would be required from the Central Telegraph Office in London to the West Central District Office, to the new office in the First Avenue Hotel, to Covent Garden, Somerset House, Fleet-street, and East Strand. Also that the existing Liverpool tube system should be extended to several offices, and an additional tube put down between the head office and the Exchange.

Submarine cables would be required to improve those existing.

Three new trunk lines would have to be erected, and also a number of minor new lines, amounting to some 800 miles of pole work, and some 50 miles of new underground work containing varying numbers of wires.

Also new wires on existing poles and in existing pipes would have to be erected to the extent of some 1,200 miles of open wire, and some 1,000 miles of wire underground.

The equipment of wires thus provided, as well as the substitution of improved apparatus on existing circuits, would require over 1,000 instruments of various kinds, and to provide power for working them would necessitate a number of battery cells approaching to 30,000.

The Post Office Telegraphs Department have been busy for months past in arranging for the construction of these lines, and manufacture of the apparatus, cables, wire, and general materials required, and considerable progress has already been made in the way of construction, but it would be difficult to give an outline of what has been done to the 31st December, 1883.

To provide clerks for working the additional apparatus brought about by the coming reduced tariff the department's school in London is actively training pupils, of which it has a full complement, and the provincial towns are also busy preparing in the same direction.

The Consolidated Telephone Construction and Maintenance Company are able to show a good return of work done and telephones supplied both to the United Telephone Company and their affiliated companies for home use, and to the Oriental Telephone Company for their extensive system in the East, comprising Calcutta, Bombay, Egypt, the Mauritius, Australia, and New Zealand. Their own affiliated companies, viz., the River Plate Telephone Company for Buenos Ayres and Monte Video have also made large demands, as well as the Edison Gower-Bell Telephone Company of Europe for Portugal, Austria, Belgium, Spain,

Digitized by Google

&c. The telephones generally supplied, excepting for home use, where the Bell telephone and Blake transmitter are chiefly used, have been either the Gower-Bell in its original form, which is largely used in all Government departments, or in combination with the Magneto-Bell, which is found to be a very useful and efficient form of telephone, the merits of the Gower-Bell arrangement being preserved, and a greater efficiency for all practical purposes by using the magneto call-bell. A great saving in battery power is also effected by this arrangement.

The demand for Magneto-Bells is greatly increasing, and there seems a general inclination to adopt this arrangement for "calling attention" as being more dependable than a battery. When in combination with the Bell and Blake instruments it also forms a very efficient telephone. The company have taken out various patents for improvements in telephones during the year—amongst others an improved transmitter; a telephone for fire alarm, police, and other public purposes, which can be placed in streets and public thoroughfares, or docks and other establishments, and could also be made available for private communication or exchange purposes, and used in streets or wherever the telephones are required to be situated. The general stagnation in the electric light business has prevented the company from doing much in that branch at present.

The London and Globe Telephone and Maintenance Company, which is the younger of the two telephone companies now existing in London, have put up some hundreds of miles of wire and cable during the past year. Their lines, we are informed, extend as far east as Stepney, westward to Notting Hill, and northwards to Islington. Cables are now being run across the Thames bridges for connection with subscribers on the Surrey side of the river, whilst other cables have been laid in the Metropolitan subways, from Queen Victoria-street to Westminster. The general manager tells us that several hundred subscribers have already promised their adhesion to the company's system, and that of these upwards of 100 firms have been placed in communication with each other through their exchange. The company has but one central exchange, which is capable of affording communication to 2,000 subscribers. The apparatus and necessary appliances are all of the description which experience in the telephone business has suggested as being absolutely requisite for affording a speedy inter-communication with subscribers. The average number of calls per subscriber is, we are assured, equal to that of any other telephone company, and exceeds that of any other company having for the time being so limited a subscription list. The lines are being rapidly extended, and especially at the moment in the direction of the docks. A large number of private lines, *i.e.*, lines between two firms, or between head and branch offices, or between offices and houses have been erected. The sale of telephone receivers has been profitably carried on, and the company are now offering transmitters. The company are now considering overtures from the provinces for licensing the use of its patents in country towns.

In the provinces the National Telephone Company have the largest extent of lines, and the greatest number of subscribers. To the business done by this company we shall refer later on. There are, however, several private firms in some of our large manufacturing towns who have taken up telephonic work in earnest, and succeeded. Among such are Messrs. Tasker Sons and Co., of Sheffield; Messrs. Davis and Son, of Derby; Mr. Sharples, of Preston; and Mr Legg, of Swansea. We should like to have referred to the work done by these firms in regular order, but the information required for this article comes to hand in such a miscellaneous way that, in order to get it in at all in time for press, we are compelled to deal with it as it comes to us.

The position of the National Telephone Company's exchanges is very well illustrated by the table given below, for which we are indebted to the courtesy of Mr. Campbell, the company's secretary in London. As will be seen the company is making sure progress, and we hope that they will continue to do so. They certainly have some painstaking men amongst their officials.

Table Showing the Number of Subscribers to the National Telephone Company's exchanges, with the managers, &c.:—

| — | No. of Exchange Subscribers as at Dec. 31, 1882. | No. of Private Subscribers as at Dec. 31, 1882. | No. of Exchange Subscribers as at Dec. 31, 1883. | No. of Private Subscribers as at Dec. 31, 1883. | Managers. |

J. C. Chambers, General Manager for English Districts.
A. R. Bennett, Superintendent of Construction for Scotch and Irish Districts.

Messrs. Tasker, Sons, and Co., who have a practical monopoly of telephonic work in Sheffield, have steadily increased the number of subscribers to their exchange. The present weekly calls number 10,988, showing an increase of 3,000 as compared with this time last year. Messrs. Tasker use nothing but overhead wires, but have taken such precautions in erecting them that they have proved sufficiently safe hitherto. The greater portion of them are of No. 11 gauge, specially covered to resist the destructive action of the atmosphere of Sheffield. Their stability is proved by the fact that no interruption in the service was experienced, even after the the recent heavy gale. Messrs. Tasker have also been actively engaged in the execution of various orders for private telephone lines in different parts of the country. Amongst others we may mention the private telephone exchange erected for

Digitized by Google

Her Majesty at Balmoral, which has given much satisfaction, and the firm have since received instructions to re-arrange and add to the telephonic system at Windsor Castle on similar principles.

Messrs. Harrison, Cox-Walker, and Co., of Darlington, were active leaders in telephone work until attacked by the United Telephone Company, since which time they have practically given it up and thrown their energies into other branches of the application of electricity. We think it a pity that this firm and others were not approached in a more friendly spirit in the first instance, and that the United Company could not see its way to selling telephones for private use. The money now lost—for a great portion of it is lost so far as telephonic enterprise is concerned—would then have gone to promote the growth of the telephone, because the company would have been in a position to charge lower rates, which would in the end have meant a greater revenue for them, as we have said higher up. Above all telephonic enterprise would have been furthered, whereas now it is struggling painfully under the weight of an incubus sufficient to crush anything of less utility and vitality than the telephone.

Messrs. Blakey, Emmott, and Co., of the Northern Telegraph Works, Halifax, and Southampton-buildings, London, have done a good business during the past year in their specialities—viz., telephonic apparatus, which they supply to most of the telephone companies. They have also turned out some good work for some of the railway companies whose contracts they have secured. We understand that their foreign trade has also increased during the past year.

Hooper's Company.—In the course of the year Hooper's Telegraph and India Rubber Works have manufactured and supplied to various departments of the Government core, single and multiple armoured cable, field telegraph wire, and cable for countermining purposes. They have also manufactured and supplied some lengths of heavy river cable to the Great Northern Telegraph Company for the Chinese Government, and some lengths of heavy cable to the Cuba Submarine Telegraph Company, for repairs, as also various lengths of insulated wire, &c., for export to Colonial and other Governments. During the year the length of cable (nearly 400 miles) manufactured by Hooper's Telegraph Works, and laid (under a twelve years' maintenance guarantee) from the steamship "Hooper," in February, 1881, between Cienfuegos and St. Iago de Cuba, has continued, as from the first, in perfect working order.

Messrs. J. Davis and Son, of All Saints Works, Derby, have connected the Derby and Litchurch Works of the Derby Gas Light Company by means of Gower-Bell instruments; the length of this circuit is over two miles. They have also connected the municipal offices at Burton-on-Trent with the Corporation Sewerage Works. In this case the distance covered is, again, more than two miles. This work was carried out in the beginning of 1883, and has worked so satisfactorily that no interruption has, as yet, taken place in the communications. Gower-Bell telephones were used in this instance. The telephone work of this firm is concluded with the mention of the connecting up of the Cannock Chase Colliery Company's central office with their Hednesford pit, which is distant some three miles and a half.

The River Plate Telephone Company, which was formed some two or three years ago in London, and who took over the telephone exchanges in Buenos Ayres from the local company in 1881, have been doing fairly well. The secretary has kindly supplied us with a few statistics which we offer our readers. At the time the Buenos Ayres Exchange was taken over, viz., August, 1881, it had 105 subscribers. On the 31st October last, the latest date to which the figures have been made up, or, rather, received in London, this number had increased to 1,071, in addition to which there were 57 private lines, making a total of 1,128 subscribers. The present rate of increase works out to about 75 per month. The Monte Video Exchange was taken in hand by the company in November, 1882, with 198 subscribers. On the 31st of last October this figure had risen to 279, to which must be added 53 private lines, making a total of 332 subscribers. The rate of increase per month for this exchange may be put down at 15, which gives the company a total monthly increase of 90 subscribers from the two exchanges. The miles of wire run in Buenos Ayres amount to 2,173, and in Monte Video to 349, or a total mileage of 2,522. These are all overhead at present. The instrument used is the Gower-Bell. The company have a concession for a cable for telephonic purposes between Buenos Ayres and Monte Video, which would run over about 110 to 120 miles of land, including several miles of submarine work when crossing the river.

Electric Lighting.—We must now take up the thread where we dropped it last week, for whatever may be our opinion as to the talents displayed in cable work, there is no doubt the general opinion on electrical work is based upon the talents displayed in electric lighting. The man who does not pose before the public is unknown, and must expect to give place to the man who manages to keep the eyes of the public upon him. The latter is seldom the better, but the public have no opportunity of comparison, hence are compelled to follow the lead of the man they know. The public know little of the higher developments of telegraphic work, but they have something tangible to appeal to them in the case of lighting, and hence assume that lighting is the be all and end all of electrical science. During the year, in order to avoid litigation, several companies have amalgamated. The most important of these are the Edison and Swan, now working under the title of the

Edison and Swan United Electric Light Company.—The following are the principal installations effected by the company during the year 1883, or at present in course of execution. It will be seen that a good deal of work has been done in lighting ships, among others H.M. Indian troopships "Malabar," "Himalaya," and "Orontes;" the steamships "Rio Pardo" and "Rio Parana," belonging to the National Brazilian Steamship Company; the steamships "Apollo" and "Minerva" belonging to the Compagnie La Platense; the "Pateena" belonging to the Tasmanian Steam Navigation Company. Four ships of the Clan line have been lighted—viz., the steamships "Clan Macarthur," "Clan Macintosh," "Clan Macpherson," and "Clan Mathieson;" also the "Takapuna" and "Wairarapa," belonging to the Union Steamship Company of New Zealand; the "Adelaide," belonging to the Adelaide Steamship Company; the steamship "Valetta," belonging to the Peninsular and Oriental Company; the steamship "Oregon," of the Guion line; the steamships "Servia," "Pavonia," and "Cephalonia" of the Cunard line; the steamship "Lonsdale," belonging to Captain James Deane. The British India Steam Navigation Company has had lighted the steamships "Rewa," "Goorkha," and "Nerbudda;" while the "Hammonia," of the Hamburg-American Steam Packet Company; the "Doric," of Messrs. Harland and Wolff; the "City of Rome," of the Anchor line; the "Tongariro," "Aorangi," and "Ruapehu," of the New Zealand Shipping Company; and the "Adriatic," of Ismay, Imrie, and Co., are fitted up with electric light.

Digitized by Google

Some of the principal installations on land are to be seen at the Holborn Restaurant, the House of Commons, Messrs. A. and S. Gatti's, at the Waterloo Station, the City and Guilds Technical College, the Criterion Theatre, at Messrs. Laing, White, and Wharton's; at the New Law Courts, and the Nine Elms Station. A number of private houses, factories, shops, &c., have been lighted, and among them may be mentioned installations at the houses of Sir M. Ridley, Bart., M.P., Blagdon Hall, Northumberland; of C. M. Palmer, Esq., M.P., Loftus, Cleveland; Captain Markham, Morland, Penrith; Messrs. Coxon and Co., Newcastle; Messrs. Rowntree and Sons, Scarboro'; and Messrs. Webb Bros., Randalstown, Ireland. To these must be added the installations at the house of T. Richardson, Esq., M.P., Yarm, Yorkshire; at Messrs. Bowyer and Priestley's, Messrs. Duff and Rowntree's, at the Great Eastern Railway Hotel, Parkeston; at Messrs. W. F. Moore and Sons', Isle of Man; at Messrs. J. H. Gartside and Co.'s, Manchester, and at Messrs. Simpson and Denison's, Dartmouth.

Few of these installations call for special remark, but it may be noticed that the installation at the House of Commons, which ran so successfully during the last Session, is being increased by the addition of about 220 lamps, which will bring the total number up to 500. The entire plant will be in readiness for the opening of Parliament on the 5th February. The Holborn Restaurant installation, consisting of plant for 500 lamps, is being augmented by additional engines and dynamos for 1,200 lamps, which will make this installation, when completed, the largest isolated plant in England. The company have at present on hand orders for lighting four additional troopships for H.M. Government—the "Crocodile," "Serapis," "Jumna," and "Euphrates"—besides various contracts for steamship plants. They are also about to carry out installations at the Cannon-street Station Hotel, also for Messrs. Shanks and Co., Messrs. Brown Bros., &c.

The fine steamship "Ruapehu," the third of three vessels lately built by Messrs. John Elder and Co., of Glasgow, for the New Zealeand Shipping Company, went her trial trip a few days ago. Like her sister ships, the "Tongariro" and "Aorangi," she is fitted throughout with the Edison system of electric lighting. The generating plant, which is in duplicate, consists of two 250-light Edison-Hopkinson dynamos running with full load at about 470 revolutions per minute, and driven by rope belting from two of J. and H. Gwynne's vertical high-speed engines.

The grand and pillar halls of the Cannon-street Station Hotel are to be lighted with about 200 lamps. A Marshall vertical engine and an Edison K dynamo will be used.

Messrs. Shanks and Co.'s new works, in course of erection at Johnstone, N.B. will have a 250-light Edison plant. The company will also lay down a plant of two K dynamos for lighting Messrs. Brown Brothers' New Tweed Mills, at Galashiels, N.B., so that, considering the necessary uncertainties which always abound during amalgamations, and the time lost in reorganisation, this work is by no means indicative of despair.

The Anglo-Brush Company.—The position of this company during the year 1883 has been one of transition and preparation. When it became evident that it was to a great extent to incandescent lighting that the companies must look for business, it became necessary that the Brush Company should have other machines than those required for arc lighting. Hence, taking the "Schuckert patents" as a basis upon which to work, and, if possible, to improve, a good deal of attention was bestowed upon the production of a machine adapted for incandescent lighting. We ought to say that the "Schuckert patent" in this country was owned by the Brush Company. The Schuckert machine has been modified by M. Mordey and others, and the improved machine is now known as the "Victoria." In addition to this machine, the company has acquired a new incandescent lamp, and is thus in a position to enter the field of incandescent lighting. With regard to arc lighting, the following are among the more important installations carried out last year:—The supply of sixty "arc" lamps to the Spanish Royal Arsenals at Ferrol, and at Carthagena; the supply of forty "arc" lamps for the use of the new Lisbon-Berlyn Gold Mines Company, Transvaal; of dynamos and one hundred "arc" lamps of the "five ampere" type, developed during the past year, to Australia; of a second dynamo and forty "arc" lamps to Messrs. Robey and Co., Lincoln; of a dynamo and sixteen lamps to Messrs. Caird and Co., Greenock; of two dynamos and thirty lamps to Messrs. Mirrlees, Watson and Co., Glasgow, and so on.

In the city of London the Brush system is the only one of the three original competing systems which still continues in operation, and although since the commencement of the lighting in April, 1880, there have been several extinctions, they have in every case been due to the cable, inasmuch as the same dynamo is now used for the lighting as has been in use from the first. The experience now gained in cable laying should enable the company to undertake further work in street lighting without danger of breakdown. In "incandescent" lighting, the company is now undertaking, or has completed, contracts at Messrs. Courtauld's, Essex; Messrs. Isaac Holden and Sons, Bradford; Messrs. Antony Gibbs and Co., Leadenhall-street; the Rev. S. Kynnersley, Ascot; Messrs. Mirrlees, Watson, and Co., Glasgow, and numerous others; while machines capable of supplying over 1,000 lamps have been supplied to the Australasian Brush Company, who have successfully lighted the Parliament House in Melbourne throughout with this system; and others to the Austrian Brush Company, the Great Western and Midland Brush Company, the Hammond Company, &c.

Considerable attention has been paid to the department of battery charging, and the "Victoria" dynamo has been principally used by the Electrical Power Storage Company for their installations. Of this class are the machines in use for charging batteries at the Gaiety Theatre, the Bank of England, the Army and Navy Hotel, Westminster, Messrs. Green and Co., and Messrs. A. Gibbs and Co., City, &c.

Several very large contracts are being negotiated, and extended operations in the field of incandescent lighting may be expected during the present year.

Messrs. Harrison, Cox-Walker and Co. have been directing their attention to the production of a portable self-containing electric lamp for mining purposes. They hold that wires cannot be used, that what is wanted is a primary or secondary battery capable of sustaining a two candle-power lamp in regular action for at least ten hours. The apparatus should be easily removed and inexpensive. This firm has in fact specially devoted its attention to electricity as applied to mining purposes.

The Gulcher Electric Light and Power Company has been engaged chiefly in the execution of export orders. At home the lighting at Lord Durham's coal drops at Lambton has been extended, as has the lighting at Messrs. Morewood and Co., Woodford Ironworks, Soho, Birmingham; an installation is in progress at Messrs. Jack's shipbuilding yard at Seacombe, but the most important work is considered to be that at Messrs. Badart Frères' Oil Mills, Rotherhithe. These

Digitized by Google

mills were destroyed by fire some time ago, and are being rebuilt on an extended scale. The work has been carried on day and night by the aid of Gülcher arc lamps; at present some twenty of these lamps are used with good effect. The mills are to be lighted throughout, as are the offices and house attached. Several orders have been executed for Canada, and in India this light is used by the contractor for the railway bridge across the Ganges. The contract for the lighting of the Lyttelton Harbour in New Zealand has, we understand, been given to this company. The English Government has given an order for one of the Gülcher machines, the report of the Committee of Royal Engineers, founded upon experiments carried out at Chatham, being favourable, Captain Cardeu, in fact, having reported that the machine had given "most excellent results."

Messrs. Tasker and Sons, of Sheffield, are fitting up an installation permanently for Messrs. J. Rogers and Co., it having been found, after a thorough trial, that the electric light is greatly superior to gas in the various departments of this firm's business, and especially in the assortment and distribution of the various qualities of polished ivory for cutlery purposes.

Mr. J. H. Greenhill, the agent for Messrs. Crompton, at Belfast, has carried out several permanent installations during the year. He has also commenced the manufacture of machines known as the Greenhill-Bürgin, under license from Messrs Crompton. The following installations are of interest, showing as they do the class of works in which electric lighting is making its way. The machines used in these installations are mostly of the Bürgin type, and are either known as Crompton-Bürgin or Greenhill-Bürgin :—Messrs. Guiness, Son, and Co. had their cask department offices lighted with 68 Swan lamps ; the flour mills of D. and W. Carmichael (Belfast) are lighted with 68 Swan lamps ; those of Messrs. W. J. Shaw and Sons (Limerick) with 80 such lamps, with a second installation of 120 lamps ; and those of Messrs. J. Furlong and Sons (Fermoy) with 68 Swan lamps. Then the great shipbuilding firm of Harland and Wolff, of Belfast, have been supplied with machines for 26 Crompton arc lamps, also with 168 Swan lamps, worked from two sets of Siemens machines. The woollen mills of Messrs. O'Brien (Cork) are lighted by 180 Swan lamps; the flax mills of Messrs. J. and T. M. Greeves (Belfast) with 120 lamps. Some of these installations are not quite complete ; that of Messrs. Guiness was finished at the close of the previous year.

(TO BE CONTINUED.)

## TRAIN LIGHTING.

One of the most unsatisfactory systems of lighting is that ordinarily adopted for trains. Many travellers supplement the light stingily provided by the companies with candles from their own store and at their own cost. Probably the railway companies wish every traveller would carry his own torch, so that the necessity of providing any light would be among the things of the past. Perhaps there are a few—nay, we will say there are a few—railway managers who see that comfort of passengers has something to do with dividends to shareholders. The use of the electric light has suggested itself to such managers, and here and there experiments have more or less successfully been made. The experiments have usually been connected with batteries, either primary or secondary, but we have recently recorded a new departure. Mr. W. H. Massey, of Twyford, has charge of experiments which are being carried out under Lord Sackville Cecil for the Metropolitan District Company, in conjunction with the Swan Company, Mr. J. S. Forbes being chairman of both companies. The experiments have been carried out on the short shuttle train running between High-street, Kensington, and Putney Bridge. The train is fitted with 28 Swan lamps, including the rear signal lamps of the brake van ; but as the machinery is intended for use with a longer train about the same number of lamps are fitted in a luggage van, so that the total cost of working the full complement of lamps required in some of the ordinary trains may be arrived at during these trials.

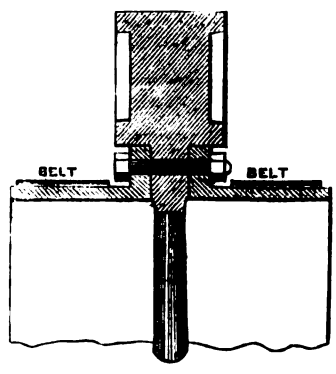
A Siemens compound-wound dynamo supplies the current for between 50 and 60 lamps of 20 candle-power each, at an E.M.F. of 48 volts, and is driven at 550 revolutions by a Willans patent three-cylinder engine, which is coupled up to it directly. Steam is supplied from a small horizontal tubular boiler, which, with the whole of the machinery, water tanks, coal box, &c., has been very neatly arranged within a London, Chatham, and Dover luggage van by Messrs. Willans and Robinson, of Thames Ditton, under the superintendence of Mr. Vincent Allpress.

We understand that there are many reasons for using a separate van at present, but should the engine and dynamo be found in practice to need little attention, it is probable that the plan originally suggested by Mr. Massey will be adopted, and that the machinery will be fixed on some part of the tender, so that steam may be taken from the locomotive boiler of the train. This arrangement would naturally cost less in the first instance, and the working expenses would be greatly reduced, as the services of an extra stoker would not be required.

Everthing has been running very satisfactorily since Thursday last, from 3 p.m. to midnight daily, and the consumption of coal is so small that after making a fair allowance for lamp renewals, the electric light will prove cheaper than lighting by oil, and may possibly compare favourably with the best systems of compressed gas.

## THE EDISON COMPANY'S INSTALLATION IN MOUNT-STREET, MANCHESTER.

The lighting of the Theatre Royal, Manchester, has for the past eighteen months been successfully provided by the Manchester Edison Company, whose dynamos are being driven by a pair of engines supplied by Messrs. Mather and Platt, of the Salford Iron Works, a firm rapidly associating themselves with the cause of electricity. A surplus of power has been provided guaranteeing the effectual driving of the several dynamos.



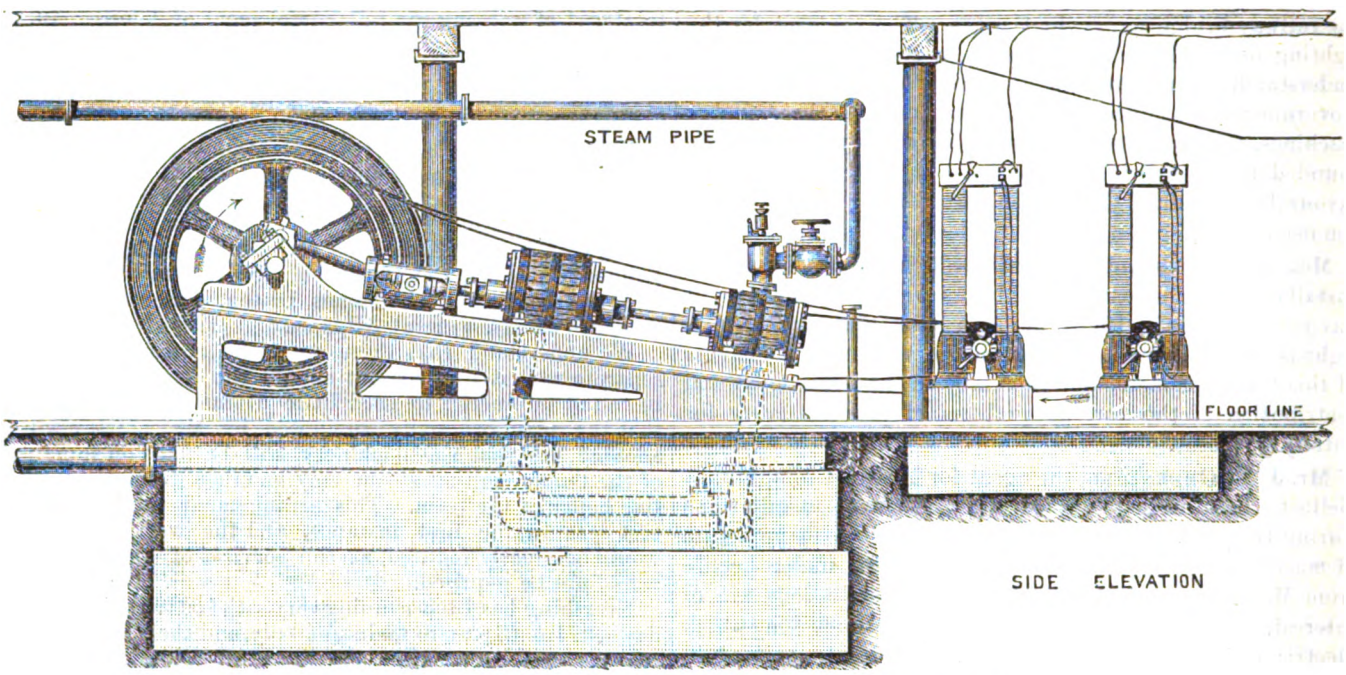
Section showing method of Bolting Driving Pulleys to Fly-wheel.

The installation is placed in the basement of the warehouse at the corner of Mount and Windmill streets, in front of the central station, and consists of engines, boilers, and dynamos in duplicate for 500 lights. The boilers are of the locomotive type, three in number, working at a pressure of 120lb., and are placed in a fire proof room. The contents of combustion pass through a flue into a chimney made of

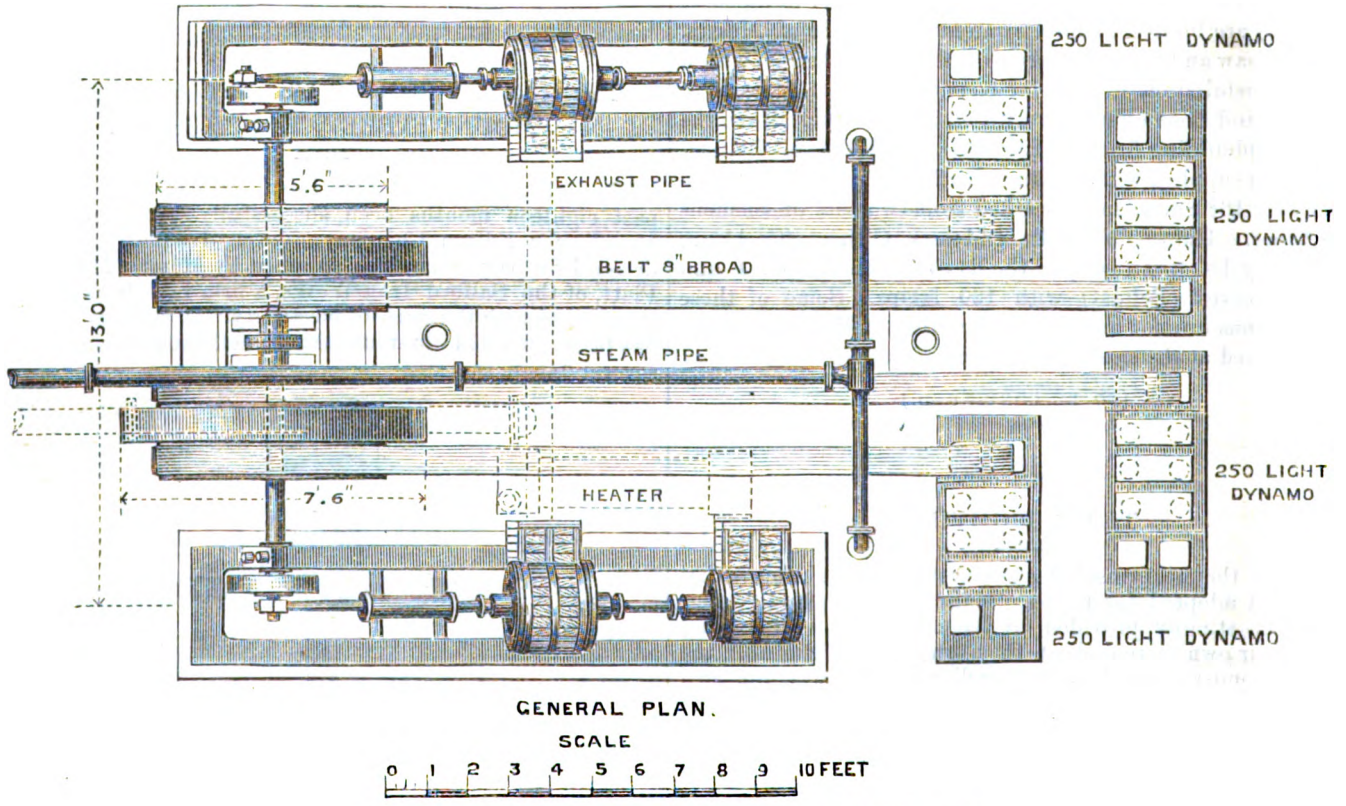
Digitized by Google

wrought-iron tube lined with fire brick, 3ft. diameter in the clear, the chimney being placed in the well hole of the warehouse and carried to the top of the building. The engines are of the class called "compound tandem," in duplicate, placed on iron frames at an angle elevating the fly-wheel and expansion valves to each cylinder, adjustable by means of a small hand-wheel, with right and left hand screws upon the valve spindle.

The cross-heads are circular, and turned to fit; cylindrical guides, similar to those usually used by Messrs. Mather and



Machine Room at the Mount-street, Manchester, Installation.—Side Elevation.



Machine Room at the Mount-street, Manchester, Installation.—Plan.

pulleys, in order that the belts may clear the floor line and dynamo frames.

The diameter of the high-pressure cylinders is 12in., and the low-pressure 19in., with a stroke of 16in., running at a speed of 190 revolutions per minute, fitted with variable Platt; and the governors are of the ordinary quick-speed "Porter" type, working the equilibrium valves, of the pattern made by this firm.

The dynamos are four in number, each of 250 lights, and are worked in pairs driven direct from the engines by 8-in.

Digitized by Google

patent link belting. The pulleys for driving the dynamos are bolted to either side of the fly-wheels, as indicated in the annexed section, so that the bosses of the fly-wheels are the main supports.

One engine is used nightly for the required 500 lights, and the other is kept slowly moving, so that in case of necessity it may take up its duty. The manner in which the alternate action is effected reflects very much credit upon the makers of these engines, we having frequently witnessed the interchange of power without causing a perceptible alteration in the lights.

The engines are thoroughly well designed. Our drawings illustrate the installation in elevation and plan, the latter view showing the coupling of the shafts, which at present run free of each other.

## CORRESPONDENCE.

### THE PHYSICAL THEORY OF THE GRAMME MACHINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I observe with some dismay that the first portion of the third paragraph of my contribution under this heading is in bad grammar and worse taste—since I am by implication made to signify that I consider myself something more than an "average electrical *savant*." I must therefore beg permission to state most emphatically that this portion of the article in question is not printed as it was written by me.

In reference to the diagram, it might be objected that the amperian currents at the poles of the field magnets are in reality—by reason of the deflective influence of the armature—at right-angles to the direction indicated. This fact, however, would in no wise affect the explanation of the action of the machine so far as the effective current is concerned. It signifies merely that *two* inverse and *two* direct currents exactly neutralising each other (instead of *one* in each direction) are produced at each pole by the "cutting of the lines of force" when the coils of wire pass the poles.

It may be of interest to point out that, at the period when the Gramme machine was first introduced into this country, Mr. Robert Sabine very clearly pointed out, in the *Mechanic's Magazine*, that the Gramme armature is analogous to two batteries of equal electromotive force and resistance, having their similar poles connected and in contact respectively with the + and − collectors. M. Fontaine also, in his work, *La Lumière Electrique*, showed that, if we place two bar-magnets in a straight line, with two similar poles opposed, and pass a coil of wire over the compound bar from one end to the other, we obtain currents which may be expressed as follows by the galvanometric deflections produced:—

*r. l. l. r.*

That is to say, a deflection to the right is produced whilst the coil is travelling from one end of magnet No. 1 to its "neutral point;" a deflection to the left is produced whilst the coil is passing from this neutral point and over the two opposed poles to the neutral point of magnet No. 2; and a second deflection to the right is obtained as the coil passes from this latter neutral point to the end of magnet No. 2. But no attempt was made to explain the observed effects by reference to fundamental laws; and, so far as I am aware, my article in your last issue is the only categorical explanation of the action of magneto and dynamo machines of the Gramme type that has ever been published. The various lectures in relation to these machines which I have read from time to time have been merely illustrations of the leading of the blind by the blind.—Yours, &c.,

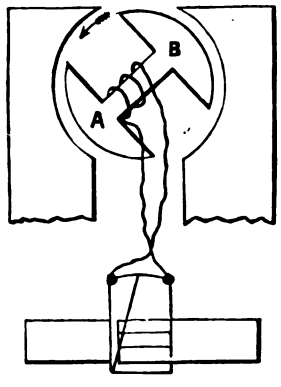
DESMOND G. FITZGERALD.

[We must accept the responsibility of the alteration referred to. The addition of "*s*" to "*savant*" was, as might be imagined, purely accidental.—ED. *E.*]

### DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am sorry I cannot yet give Mr. Farquhar full details of my machine, but the following may be of use to him. Field-magnet—two legs, bolted to iron bed plate; cores, 6in. by 4½in. by ¾in. The wire is wound on in eight layers, 28 turns to a layer, 448 turns for whole magnet; length of each turn 14in. on average; weight of wire 2lbs. 2oz. on each leg (No. 18 double cotton covered); total resistance of field magnet 3 ohms.



Armature—length 5¾in., diameter 1⅞in., size of core 4¾in. by 1¼in. by ¼in. The armature is wound with eight layers of No. 18 wire, each layer having 15 turns, 120 turns for the whole. Length of wire about 90 feet, resistance ·6 ohm.

The field-magnet is joined as a shunt on the armature. When run at about 2,000 revolutions a minute the machine will light a 10 candle-power, 20 volt lamp, to the full power; at a lower speed, about 1,800, it will light a high resistance 5 candle-power, considerably over the nominal power. When a lower resistance than about 5 ohms is put in there is very little current in the external circuit.

If Mr. Farquhar wants his machine for ordinary experiments, I should advise him to wind his field-magnet, as I am now doing, with 5lbs. of No. 16 wire (1 ohm), and put No. 20 wire on the armature, joining the magnet and armature in series. I find a shunt-wound machine is no good for experiments unless the external resistance is high, 5—20 ohms, although it is best for incandescent lamps.

The armature should be wound and connected up as shown in the diagram, or the machine will not work. The wire should be wound from A towards B. It is often necessary to put a battery on to the field magnet before starting the machine.

I bought all the parts of my machine at Messrs. Oppermann Bros'., 172, St. John's-street, Clerkenwell, where I should advise any one to go who wants a well-made machine at a very low price.—Yours, &c., W. M. H.

Claremont House, Lee.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As Mr. Oldham suggested, I should say the fault lay in the formation of wire wound on the armature and field-magnet. For a "series" dynamo the resistance of field-magnet should be somewhat less than that of armature, while for "shunt" dynamo the resistance of field-magnet should be from 200 to 300 times that of armature.

He gets best results when connected up for "series," as then his wires are more nearly in proper proportion than when connected up for "shunt." Resistance of so small a machine will be necessarily high, and I would suggest for A coil No. 14 B.W.G. 60 yards; and for B coil No. 30 B.W.G. 300 yards, and at least 1,400 revolutions.—Yours, &c.,

Fall River, Mass., Dec. 21, '83. A. R. B.

### HERR SAUER'S PHOTO-ELECTRIC BATTERY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I tried this a few days ago, and at first could get no

Digitized by Google

current, then, thinking the porous pot might perhaps not be thoroughly permeated with the copper solution, I removed it and substituted a small glass vessel, a minim glass, nearly full of quicksilver, on which I floated the silver sulphide, put quicksilver in the outer glass, of course seeing that the minim glass was *covered* with solution, put one platinum plate into each vessel, and connected. I got a small deflection, together with, at first, a smell of sulphuretted hydrogen, but the battery was utterly indifferent to light, gas, or day light. After the first minute or two the smell disappeared. If any of your readers have successfully worked this very interesting battery I shall be much obliged if they will tell me where I was wrong.—Yours, &c., DISAPPOINTED.

## THE "AMPERIAN CURRENT" HYPOTHESIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I venture to submit that it is now quite time we gave up the attempt to elucidate magnetic phenomena—whether in dynamo machines or elsewhere—upon the basis of the "Amperian current" theory. Brilliant and ingenious as that theory undoubtedly is it has seldom been regarded as much more than a good working hypothesis, and had any one ever been inclined to suppose that it offered a true physical explanation of the constitution of magnets surely the recent splendid researches of Professor Hughes must have convinced him of its fallacy.

Moreover, it is well known that in one particular case of the juxtaposition of magnets that theory requires a repulsion between opposite or an attraction between similar poles; which, I need hardly say, does not accord with the facts.

The "lines of force" method, on the other hand, although less easy to apply, is based upon ascertained facts, and does not depend upon any theory whatever as to the *cause* of magnetic phenomena. If, then, these different methods give results at variance with each other, or offer different explanations of the same phenomenon, surely the "Amperian current" exposition must be the one to go to the wall.—Yours, &c.

W. H. SNELL.

Liverpool.

## SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We note that in your well-written leader of last week and the paragraphs which followed it you refer to the "Planté" and the "Elwell-Parker" secondary battery as two distinct types, whereas they are one and the same thing.

The original Planté battery, than which no better has since been produced, was, commercially, of little value, on account of the time and cost absorbed in producing it.

This secondary battery has been in use for about *twenty-three years* without any of the plates wearing out or becoming useless.

Monsieur Planté has, since 1860, tried every means he could think of with a view to hastening the "formation" and reducing the cost of this battery. He tried many years ago nearly all the processes which have swelled the patent list for the last two years, and came to the conclusion that the pure lead of the plate itself must be acted upon, as in his original cell, in order to produce any lasting power as a secondary battery.

The outcome of this was his great discovery in 1882 of the power of nitric acid in hastening the "formation" of the plates, and producing, after only one or two reversals of the current, a cell in every way equal, in fact precisely similar, to the original couple—no better and no worse.

The Elwell-Parker patent includes the use of sulphuric acid with the nitric, by means of which the use of the latter is economised. The result is practically the same, as the sulphate formed upon the plates by the latter process does not remain long, and it is the ulterior effect of the nitric acid which is so valuable in both cases.—Yours, &c.,

THE WOLVERHAMPTON ELECTRIC LIGHT, STORAGE, AND ENGINEERING COMPANY.

Patentees of the Elwell-Parker Battery and Proprietors of the Planté Patent.

January 7, 1884.

## THE MEDITERRANEAN EXTENSION TELEGRAPH COMPANY (LIMITED).

An extraordinary meeting of the shareholders of this Company was held at the Cannon-street Hotel on the 9th inst. "for the purpose of considering a provisional agreement made between the liquidators of the Mediterranean Extension Telegraph Company (Limited), of the one part, and the Eastern Telegraph Company (Limited), of the other part, for the sale and purchase by the Eastern Telegraph Company of the telegraph lines, concessions, and other property belonging to the Mediterranean Extension Telegraph Company, and to pass such resolutions thereon as to the meeting may seem expedient." The meeting was convened by the liquidators, the Hon. Ashley Ponsonby and Mr. John G. Griffiths, the former of whom presided.

The SECRETARY (Mr. Tombs) read the notice convening the meeting.

At the request of the CHAIRMAN,

The SOLICITOR (Mr. Campbell) read the agreement, which set out that the property to be sold was the submarine line between Otranto and Sidari, the land line between Sidari and Corfu, and the submarine line between Pozzalo and Malta, "with all the lands, offices, buildings, machinery, lines, instruments, plant, fixtures, appliances, and appurtenances to the same belonging." The two concessions of May, 1859, and July, 1861, with all the rights and liabilities attaching to them, were included in the purchase, the proposed price being £35,000 in 4 per cent. mortgage debenture stock of the Eastern Company, to be taken at par. The Eastern Company were to bear their costs as purchasers, and the Mediterranean Company would bear their expenses as vendors. The Mediterranean Company undertook to carry on at their own risk and cost, and work the lines for their own benefit, up to the time of completing the purchase, which had been fixed at the 1st March next. If, owing to any delay, the purchase could not be completed by that date, then it was to be postponed to such period as the liquidators and the Eastern Company might agree on. The agreement was made subject to the approval of the shareholders and to the consent of the Italian Government. There was a proviso that if the shareholders did not approve it, or the consent of the Italian Government to it should not be obtained before the 31st March, or such later date, if any, as might be agreed on, the liquidators on the one part, and the Eastern Company on the other, had power to put an end to the agreement on giving to the other of them one calendar month's notice in writing. There was also a proviso that if there was any modification made in the concession, and the Eastern Company were enabled to obtain any better terms, or any extension, it was not to affect the terms the Mediterranean Company were to receive for the existing concessions.

Mr. GOULD thought that the document read was of an important nature, and, on the part of a section of the shareholders, he felt inclined to say that it ought to have been in the hands of the shareholders for consideration before the meeting. He confessed that he was unable to come to a decision on the spur of the moment, and to say that the agreement was one which they ought to consent to. In saying that, he was sure that the liquidators had done all they could to obtain a proper agreement.

The SOLICITOR: The agreement, in a few words, is simply—you have a property to sell. The liquidators propose to sell it to the Eastern Company, who propose to give you £35,000 in 4 per cent. debenture stock for it.

Mr. BURT: If the Italian Government consent to the transfer.

The SOLICITOR: Yes. Probably the best course will be for the resolution to be moved and seconded, and then the discussion can follow. The resolution is "That the provisional agreement between the liquidators of this Company and the Eastern Company for the sale and purchase of this Company's submarine lines, concessions, and other property having been read to the meeting, it is resolved that this meeting do approve of the same, and authorise the liquidators of this Company to take the necessary steps to carry the same into effect as speedily as possible."

The CHAIRMAN then said he wished to say a few words as to how the liquidators had come to the opinion that they had better sell the Company's property. About a year ago they came to the conclusion that they would not accept the £40,000 which at that time was offered by the Eastern Company under certain conditions, and the late Sir James Carmichael and he expressed their views as shareholders, and not as directors, that it would be better not to accept the offer. At that time they had an idea—or, rather, more than an idea—that they would be able to sell the undertaking of the Company on better terms to other parties, from whom, however, they had never had a tangible offer, or any means of ascertaining what they would give. That, therefore, had fallen through. The shareholders must also remember that the Trieste cable had been laid by the Eastern Company, who to a considerable extent had tapped the Mediterranean Company's earnings, and they were in a position—which every year might have become worse—of being surrounded by a hostile company. Considering, therefore, that their concessions were getting shorter, and their cables older, they had thought it would be advisable again to enter into negotiations with the Eastern Company. Mr. Griffiths and he had accordingly long and earnest negotiations with Mr. Pender, the solicitor, and other gentlemen representing the Eastern Company, and at length they had arrived at the terms which were before the meeting. For his own part he did not see that any other terms were likely to be obtained—he was sure, indeed, that they would not get more. They had been crippled by the petition against them, and if the question had been asked in court they would have been obliged to say that, if they paid their preference shares, they would have nothing left for division among the ordinary shareholders. On these grounds also they thought it would be better not to fight that petition if it went into court, but to try and sell the Company's undertaking for what they could. They had now the tangible offer referred to, and it was for the shareholders to decide whether they would accept or reject it. That was the simple object of their meeting. As to the division of any assets they might have, that question must be left for a further occasion and to the decision of the Court when they went to obtain the ratification of the agreement. It had been asked whether they could not put off the agreement for some little time, but he thought they could not, as they would have to go before the Court. They would have to lose some time with the Court. With any delay they might lose their chance of selling, and he would remind them that they had obtained a tangible offer. Any delay, too, prolonged the risk they ran in working

Digitized by Google

their cables themselves. As Mr. Campbell had said, the real question was whether or not they were prepared to sell their property for £35,000 of debenture stock. The liquidators had come to the conclusion that it would be best for them to accept the offer. He concluded by moving the resolution as above.

Mr. J. G. GRIFFITHS having briefly expressed his pleasure at seconding the motion,

Mr. GOULD said he would not say that the £35,000 offered by the Eastern Company was not a fair sum to pay to this Company for what they had to sell, but he repeated that he would have been glad to read the agreement. He would have preferred the offer much more had 5 per cent. debentures been offered, for it was to be remembered that the £35,000 offered them in 4 per cent. debentures did not represent that amount on the market. The 5 per cent. debenture stock of the Eastern Company was about par.

Mr. GRIFFITHS: No, it is above par.

Mr. GOULD: The 4 per cent. stock, he supposed, was about 80.

Mr. GRIFFITHS: 95.

Mr. GOULD said he was glad to hear this, as it brought them very much nearer to an agreement. He, however, saw the 5 per cent. stock quoted a few days previously at 101.

Mr. GRIFFITHS stated that that quotation applied to debentures redeemable in a very short time, whereas the 4 per cent. debenture stock was permanent, and, as he had said, was now quoted at 95. Therefore the offer made represented £33,250.

Mr. GOULD thought there would have been no difference as to accepting the offer if it had been made in 5 per cent. debenture stock.

Mr. BAKER (of the firm of Messrs. Lawrence, Plews, and Baker), who was acting for certain shareholders, requested that he might see the agreement, and the document was at once passed to him.

The CHAIRMAN, in answer to Mr. W. Ford, stated that they would continue to work the Company up to the time of sale, of course being liable until then for any break which might occur in the cables.

Mr. FORD observed that a break might take half or even all their reserve fund to repair.

A SHAREHOLDER, holding both ordinary and preferred shares, said he had listened very attentively to the agreement, and he was convinced that it was to the interest of the shareholders that it should be carried out.

The CHAIRMAN said he was sure that Mr. Burt would say that the liquidators had done everything they could to get a higher price. They began by asking £50,000, but they could not obtain more than £35,000.

Mr. BURT: And you got £10,000 too much.

The CHAIRMAN, in reply to a question, said he could give no opinion as to how the reserve fund would be divided.

Mr. GRIFFITHS, in further reply, stated that the reserve fund and the undivided assets would amount to about £15,000, in addition to the £35,000 to be received from the Eastern Company.

Mr. FORD observed that every day the cables were worked by this Company they were liable to see the reserve fund diminished by the cost of repairs in the event of a breakage.

Mr. GRIFFITHS stated that the last break was in September.

Mr. CUTHBERTSON asked whether the particular question under consideration, the transfer of their property, had been confined entirely to the Eastern Company, or whether it had been brought before a company called the Mediterranean Company.

The CHAIRMAN said he knew of no such company.

Mr. CUTHBERTSON observed that perhaps it had been merged in some other company.

Mr. GRIFFITHS: Long ago.

Mr. CUTHBERTSON inquired whether anything had been done with French or Italian people?

The CHAIRMAN: Not with French people, but the Italians did send somer offer——

Mr. GRIFFITHS: A suggestion.

The CHAIRMAN: Yes; not an offer, but rather a suggestion.

A SHAREHOLDER said he presumed the offer was less than that made by the Eastern Company.

The CHAIRMAN replied that no money was mentioned.

A SHAREHOLDER said he thought they might have obtained better terms from some of the Italian companies.

The CHAIRMAN stated that there was a good deal of inquiry and some correspondence, but it all came to nothing.

The SOLICITOR observed that the concessions of the Company could not be transferred without the consent of the Italian Government, and it would require rather a strong lever to be brought on that Government to effect this object.

A SHAREHOLDER said he thought that this influence might be exercised better by an Italian company.

The SOLICITOR replied that he thought the people who would have most weight with the Italian Government would be those who were strongest in the Mediterranean.

Mr. GRIFFITHS, in answer to a question, stated that Messrs. Siemens had been communicated with previously (as to acquiring the undertaking of the Company), but at that time the firm would not deal. It would not, however, have done for the liquidators to have gone "hawking" about the property of the Company. They had not such a grand thing to sell, and they were very glad at getting such an offer from the Eastern Company.

A SHAREHOLDER: The agreement does not touch the reserve fund?

The SOLICITOR: No.

Mr. FORD: The rights of the preference and ordinary shareholders are not in the least affected by the agreement?

The SOLICITOR: Not in the least.

Mr. BAKER observed that, having read the agreement, he considered that the price offered was an adequate one.

A SHAREHOLDER: Suppose we accept the agreement, how soon will it be binding?

The SOLICITOR: It will be binding on us to-day.

The SHAREHOLDER: And on the other parties?

The SOLICITOR: In two or three days. In further reply he stated that the Eastern Company had approved the agreement, and were merely waiting to put their seal to it.

The CHAIRMAN then put the motion, and it was carried *nem con.*

Some discussion followed a question asked by Mr. Hurst as to whether the liquidators intended making some arrangement by way of compensation to the staff of the Company. Mr. Griffiths intimated that the subject had not been lost sight of; but as the question was outside the object of the meeting it was decided to defer its consideration until it was brought before the shareholders.

On the motion of Mr. FORD a vote of thanks was passed to the liquidators, and the proceedings then terminated.

## SOUTH AFRICAN BRUSH ELECTRIC LIGHT AND POWER COMPANY (LIMITED).

An extraordinary general meeting of this Company was held on the 4th inst. at the Cannon-street Hotel, under the presidency of Lieut.-Colonel George Coxon.

The SECRETARY (Mr. Thomas J. Seel) read the notice convening the meeting, in which the directors reminded the shareholders that at the meeting held on the 26th November last the Board recommended that the shares should be reduced from £5 to £3 each, thus leaving a liability of 10s. instead of £2 10s. per share. The present meeting had therefore been convened for considering a resolution for carrying out this object.

The CHAIRMAN said he must apologise for a mistake which had been made at the previous meeting. At that meeting the directors were asked whether at this meeting an amendment could be proposed to the resolution of the Board—an amendment embodied in a communication from the Rev. Mr. Johnson, intimating his intention of moving it at that meeting. He did not think they distinctly stated that it would be competent for Mr. Johnson or any other shareholder to put an amendment at that meeting to the resolution of the directors—indeed, as far as he was concerned, he refrained from doing so: but he would freely admit his conviction that the meeting broke up with the idea that such a course could be taken. He regretted, however, to say that that could not be done, and that that meeting could only deal with the resolution in the hands of the shareholders. He might state that since the last meeting matters looked better—at least, he would leave them to judge whether that was so by simply telling them that their last letters from their manager were more hopeful. He had had a request from the Docks Corporation at Cape Town, whose contract with the Company had lapsed, to propose another contract. The reason of the delay in making this request had been that the Dock Corporation were anxious to wait a little before a fresh contract was made, hoping, from the favour with which the light was regarded at the Cape, that the Company would get more business—and they had obtained seven more lights—and so be able to offer them better terms. The fact, however, that they had now pressed the manager of the Company to propose another contract settled the question about the popularity and efficiency of the light at Cape Town. Mr. Atkinson, who was not present, had been to Kimberley. He was a shrewd business man, and held 900 shares in the Company. He had spoken very highly of the light at Kimberley, and had said that it was better than any he had seen in England. He thought that that view spoke well for the efficiency of the officers of the Company. They had thirty-two lights on a seven mile circuit, driven by one dynamo, a fact testifying to the efficiency of the Brush system, notwithstanding that a gentleman at the last meeting had characterised it as obsolete. The Brush system, he (the chairman) maintained, "was not to be touched." He mentioned these little facts as being more or less encouraging. They had had a letter from the Anglo-American Brush Company for permission to ship direct on the 24th inst., without any further red-tapeism in the matter, in consequence of the time being short, the whole of the electrical plant and machinery required for the Lisbon-Berlyn Gold Mining Company in the Transvaal. This Company held the concession for the whole of the Cape and the Transvaal, and therefore the communication referred to had come to them. He believed this Company's commission would be 25 per cent. He had, it appeared, made an error—the permission sought was to enter into a contract with the Lisbon-Berlyn Company. This was not much in itself, but the question was, would these goldfields be a great success? If they were, a powerful company like the Lisbon-Berlyn Company would work night and day, which they intended to do, by getting the electric light; and it would be fair to assume that all the other companies would do the same. Suppose, however, that they did not, at all events there was the extension of the light in that direction, and if it went no further than the Transvaal it rather strengthened the plea of the directors for continuing to work, from this fact—that, in the Transvaal, should the Company hold on, as at present, and wait for better times, there would be a field open to them—should they eventually decide to wind up—for disposing of their Kimberley plant. They had plant there to the extent of between £5,000 and £7,000, and were they to wind up now it would simply be worth its weight in iron. The Transvaal goldfields were only about 100 miles from Kimberley. He concluded by moving the following resolution:—"That the capital of the Company be reduced from £100,000 to £60,000, the 20,000 shares already issued, constituting the present capital of the Company, being reduced from £5 each to £3."

A SHAREHOLDER: Are Mr. Atkinson's shares fully paid, or of the same denomination as our own?

The CHAIRMAN: They are all of the same category.

Mr. THOMAS DICKSON, in seconding the motion, stated that the directors were there to fulfil the promise they had made to relieve to a very considerable extent the burden on the backs of the shareholders of the uncalled liability. They had not come to ask the shareholders simply to reduce the capital and to leave a small balance to be called up, as a sort of thing to fill up any bad hole, for they had money at the bank, and were able to pay their way. By going over the accounts, too, since the last meeting, and carefully hearing from their efficient secretary how they stood as to working expenses and income, they found that they were holding their own very fairly well, indeed. As to the question of dividend, for which some of them might be looking, in the present position of the electric light that was not to be expected. What they wanted to do was to hold their own, and wait for better times. They simply wanted the small amount of uncalled capital to stand so as to meet an emergency, should it occur. A

Digitized by Google

much care would be taken of the shareholders' interests as of those of the directors—indeed, they were all in the same boat; and the 10s. a share would not be called up unless they saw a good way of utilising the money. The directors, however, did not wish the Company to be put in such a position that if an opportunity was offered to them they could not take advantage of it for the want of a little money. The directors thought they saw the "silver lining to the cloud" in the Cape of Good Hope. Like a great number of colonial places the Cape had been passing through a period of great depression, and that depression had re-acted on the electric lighting enterprise. What would certainly be of great advantage to the Company would be the mining operations, should the enterprise to which the chairman had referred be successful.

The SOLICITOR, in answer to Mr. John Taylor, stated that, as a matter of law, the shareholders at the present meeting could only say "aye" or "no" to the resolution. He would remind them that the resolution was only the first step in very complicated proceedings, and that the next step would be to go to the Court of Chancery to get their consent to it.

Mr. TAYLOR complained that the solicitor was represented at the last meeting, and that his representative had allowed the shareholders to separate with the idea that an amendment might be proposed at the present meeting.

The SOLICITOR stated that he had understood that an abstract question was put—whether a special resolution could be altered or not, as to which there had been some doubt.

Mr. TAYLOR stated that he would have moved the adjournment of the former meeting but for the erroneous impression which had been conveyed to them.

Mr. DICKSON pointed out that the directors were really in the hands of the shareholders, and that they did not wish to do anything that was against the shareholders. They could vote for the resolution or against it, and there would then be a poll. The directors held 2,000 proxies for 2,000 shares.

Mr. CLODD maintained that the position of the Company did not warrant the retention of the liability of 10s. a share, as proposed by the directors. He thought that the best course they could take would be to wind up the Company at once [No, no]. The company was a miserable failure, and why, he asked, with money in hand did the directors wish a liability of 10s. a share to be held *in terrorem* over the heads of the shareholders?

The Rev. Mr. JOHNSON protested against the ruling of the solicitor, as at the former meeting a shareholder got a statement from the solicitor (meaning the representative of that gentleman) that no resolution should be submitted to the present meeting which did not allow the shareholders to reduce the capital to £2 10s. a share.

The CHAIRMAN dissented from this view of the question, and asserted that it was not understood that whatever resolution was framed by the directors would be susceptible to an amendment of the nature indicated by Mr. Johnson. What was understood was that whatever the directors' resolution might be it would be competent for a shareholder to propose an amendment in one form or another.

A SHAREHOLDER: But now the solicitor says that we cannot do that.

The CHAIRMAN: It was unfortunate ("very"). He had explained the reason. He wished that the shareholders had the power to propose an amendment, for, as it was, the directors would only have extra trouble.

The Rev. Mr. JOHNSON stated that he had taken a barrister's opinion on the matter, and he was of opinion that an amendment to the effect he had communicated to the directors could be put to the meeting; and he thought the shareholders were entitled to say distinctly that, should their interests suffer by the chairman refusing to allow the amendment to be put, they would hold the directors legally responsible for any loss they might thereby sustain. His proposal was strictly in accordance with the Company's Articles of Association, and if from any technical causes it could not be put he held that the secretary should have informed him. He then moved as an amendment "That the capital of the Company be reduced to £2 5s. a share."

Mr. DICKSON: Can you not negative the resolution?

The Rev. Mr. JOHNSON: But what will you do then? Will you call another meeting?

Mr. DICKSON stated that if the directors were beaten on the poll they would call another meeting to reduce the capital as stated. Mr. Johnson had appealed for proxies, like the directors, and the poll would show who had the greatest support.

The CHAIRMAN asked the shareholders to try and consider that the table which was between them did not divide two hostile camps. They wished in every way to meet the views of the shareholders, and all that they had done was from their knowlege of the circumstances of the Company. The question was would the shareholders throw away all that they had spent in connection with the Company for the sake of a few shillings, or would they wait a little, and take the chance of getting their money back? The resolution must be voted on, and out of their sense of responsibility for the interests of absent shareholders, the directors could not accept the rejection of the motion without going to a poll. Immediately after the poll had been decided the directors would call a meeting and acquaint the shareholders of the result of the poll.

Mr. HARVEY contended that the information which the chairman had just given as to the prospects of the Company was not more correct than previous information which had been given to the shareholders. There was a certain amount of cash in hand, the future revenue of the Company was altogether doubtful, the future expenditure was altogether certain; and, therefore, looking at the affair as a business man and as a colonist, he advised them if the directors could give them 10s. a share to accept it.

A SHAREHOLDER: Or even 5s.

Mr. HARVEY: I am not prepared to accept that.

The CHAIRMAN was about to put the resolution, when

The Rev. Mr. JOHNSON moved his amendment, as before, stating that he had said £2 5s. a share, in order that the directors might return them 5s. a share, which, he said, would leave the directors £5,000 to work with. There was £7,500 still at the bank.

The SECRETARY: No, no.

The Rev. Mr. JOHNSON: Then when was it taken from the bank?

The SECRETARY replied that money had been taken from the bank for the ordinary business of the Company. He afterwards read a statement, showing that on the 30th June the Company had cash £8,069, and debtors £3,043. Deducting bills payable and creditors, there were available assets of about £10,000. They had now cash £5,600, and debtors he estimated at £4,000. They had also shipped stores and plant to the amount of £846. They had creditors now to the amount of £916.

Mr. TAYLOR thought that "squabbles" would not tend to benefit the Company. He thought the directors could see that the feeling of the shareholders present was in favour of a reduction of the capital to £2 10s. a share. He held that it was altogether the solicitor's fault that the shareholders on the last occasion were allowed to go away with a false impression. He urged that the resolution should be put, and that if it were negatived—as he was confident it would be—the directors should take that expression as the resolution of the shareholders, and call another meeting to propose the reduction of the capital to £2 10s. a share.

The CHAIRMAN stated that the directors were precluded by law from putting the amendment. He then invited those who approved the resolution to signify the same in the usual manner, when only two hands were held up in its favour. On being put to the contrary the resolution was lost by an overwhelming majority. He then demanded a poll, which was opened at once for the convenience of those present, and after some discussion on the point it was finally arranged that the poll should be kept open at the Company's offices until the following (last) Tuesday.

## NOTES.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 11th January amounted to £3,500.

APPOINTMENT.—Mr. John W. Lieb, jun., formerly electrician at the Edison central station in New York, has been appointed chief electrician to the Italian Edison Company, Milan.

TO BE WOUND-UP.—A petition for the winding-up of the Harrogate Electro-Hydropathic Company has been presented, and is directed to be heard before Mr. Justice Chitty to-day (Saturday).

TECHNICAL SCHOOLS AT NOTTINGHAM.—The technical schools in connection with the University College, Nottingham, will be formally opened by Sir Frederick Bramwell on the 24th inst.

TELEGRAPHIC EXTENSION IN WESTERN AUSTRALIA—The latest news from this colony is to the effect that the Northampton to Roeborne telegraph construction party are doing good work. About sixty miles are now completed.

NEW BOOK.—Mr. A. A. Campbell Swinton, of Newcastle-on-Tyne, has a book in the press entitled "Electric Lighting," which will shortly be published by Messrs. Longmans, Green, and Co., of Paternoster-row, E.C. It will be practical rather than theoretical.

HUDDERSFIELD INDUSTRIAL EXHIBITION.—The only prize medal (silver) awarded at the Huddersfield Industrial Exhibition for Electrical Apparatus and Lightning Conductors has been obtained by Messrs. W. D. Berry and Sons, of Brook-street, Huddersfield.

SALE.—We notice that another sale of electrical plant is pending. Messrs. Hudson, Smith, Williams, and Co. are to sell the plant, machinery, &c. of the Pyramid Electric Company on the 24th inst., at the company's works, Whitecroft, near Lydney, Gloucestershire.

INTERNATIONAL FISHERIES EXHIBITION.—The commissioners have awarded a diploma of honour to Lord Elphinstone and Mr. Charles W. Vincent, F.R.S.E., for their services in connection with the electric lighting at this exhibition, where the Elphinstone-Vincent dynamo was employed.

ELECTRIC BICYCLE AND ATHLETIC CLUB.—This club, under the auspices of the controller and other officers of the Central Telegraph Office, gave their second annual concert last Saturday evening, at the South-place Institute, Finsbury, before a good audience. The entertainment passed off very successfully.

EARTHQUAKE IN SICILY.—A Reuter's telegram dated Rome, Jan. 12, says that telegrams received there from Catania announce that a rather severe shock of earthquake was felt at Linguagrossa and Castiglione on the 11th inst., accompanied by an undulatory movement of the soil. No loss of life is reported.

CURIOUS PHENOMENON.—At 5:25 p.m. on Friday, the 11th inst., a ball of light, shaped like a pear, with the broad end downwards, was seen from Fort William as if suspended midway between Ben Nevis and the Caledonian Valley. It descended till near the surface of the earth, and then it burst, lighting the whole valley. In colour it resembled the electric light.

THE VIENNA EXHIBITION.—The Emperor of Austria has bestowed decorations on Count Hans Willozek, the Hon. President of the Electrical Exhibition, on Baron Erlanger, Professors Pfaff Stefan and Grimburg, and Major Obermayer, members of the committee, as well as on Herr Ludwig-Piette, the inventor of the Pilsen lamp, and many others.

PROPOSED AMALGAMATION OF GAS COMPANIES.—The Board of Trade, after consideration of the details of the scheme for the amalgamation of the South Metropolitan Gas Company with the Gas Light and Coke Company, and looking to the almost unanimous opposition of the Metropolitan local authorities, have decided not to give their approval to the scheme.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—We are informed that, pending the receipt of accounts from the West Coast of South America, the directors of this company have declared out of the past year's earnings, which show a considerable increase over the earnings of the previous year, a dividend at the rate of 4 per cent., or 8s. per share, on the ordinary shares of the company.

UNDERGROUND WIRES IN FRANCE.—Our neighbours are evidently determined not to lag behind Germany in the matter of underground wires. According to a statement just prepared it appears that the French Government have determined to lay a further length of 7,296 kilometres (rather over 4,530 miles) of underground cables, the cost of which is estimated at 54,000,000 francs, or £2,160,000.

ELECTRIC LIGHTING AT DUNDEE.—On Wednesday week the Dundee Fine Art Exhibition was finally closed. As we have already mentioned, the galleries in which it was held were lighted by the Northern Electric Light Company of Dundee. Great praise has been bestowed on this company and its manager, Mr. Loring, for the very efficient manner in which this lighting has been carried out.

ELECTRIC LIGHTS ON THE STAGE.—Mr. Augustus Harris has introduced the electric light into the transformation scene at Drury Lane pantomime. The lights are fixed on to the fairies' heads, and at a given signal are turned on simultaneously with very great effect. The lamps, batteries, and fittings have been designed and manufactured by Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, E.C. A very small secondary battery is used, weighing about 1½lb.

SHIP LIGHTING.—The ss. "Valetta," built by Messrs. Caird and Co., of Greenock, for the P. and O. Company, to whose line she is the latest addition, went for her trial trip last week. Her principal dimensions, &c., are as follow:—Gross tonnage, 5,000; length, 421ft.; breadth, 45ft.; depth, 37ft.; carrying capacity, 4,000 tons. She is a flush deck ship, and is built of steel. Her saloons and cabins are luxuriously fitted up, and will be lighted on the incandescent system by the Edison and Swan United Company.

NOVEL LAMP-POSTS.—At several corners in Launceston, Tasmania, says the *Colonies and India*, the ordinary lamp-posts have been superseded by the poles recently erected in connection with the telephonic exchange. The supply-pipe has been carried up the front of the telephone post, and the lamp is supported, at a sufficient height to be above the risk of injury from vehicles passing under it, on a neat iron bracket projecting from the post. The new style is neat, and seems a decided improvement on the old serviceable, but certainly not ornamental, style of lamp-post.

THE SUAKIM CABLE.—A telegram from the *Standard's* Cairo correspondent, dated Sunday night, said:—"The Eastern Telegraph Company have at length obtained the contract for the Suakim cable, and orders have been sent to

Digitized by Google

Suez for the steamer "Chiltern" to proceed at once to Suakim and lay the line, which is expected to be in working order in about ten days." On the following day (Monday) the Eastern Telegraph Company notified that the ss. "Chiltern" was to sail that day from Suez to connect Suakim with the Company's stations at Suez and Aden. With favourable weather the Company anticipated that communication should be established in about eight days' time.

Overhead Wires.—We print in another column a full report of the proceedings at the Local Government Board on Friday last, when a deputation of private property owners and their agents met Sir Charles Dilke and laid before him their views on the overhead wire question. The answer of Sir Charles Dilke is reassuring. "This matter is continuing to have my careful attention," he says, and implies that the question will be brought before Parliament during the next Session. The President of the Local Government Board quite agreed with the deputation that some control should be had over "abandoned wires," that is, private wires which have fallen into disuse and belong to no one, and which are far more dangerous than the live wires, which are inspected regularly, or should be.

Edward Davy.—We now have before us a fairly full report of Mr. Ellery's paper on Edward Davy and his inventions, recently read before the Royal Society of Victoria, and to which we referred in a note in our last issue. We need not quote that part of Mr. Ellery's paper relating to Dr. Davy's inventions, as it is simply an abstract of Mr. Fahie's articles in our columns. It appears, however, that Dr. Davy was the founder not only of the Philosophical Institute at Melbourne, but also, to quote Mr. Ellery, "the parent of this (the Victorian) Royal Society." In conclusion he adds, "This society will, I am sure, feel proud to know that it may rank among its founders the name of Edward Davy, the almost forgotten pioneer and inventor of the electric telegraph, and at the eleventh hour to do what honour to him it may be within its province and power to do." How readily the members present fell in with Mr. Ellery's views we have already mentioned in our last week's Notes. Let us hope that this hearty though tardy appreciation of his services will compensate Dr. Davy in some measure for the disappointments of past years.

The J. B. Rogers Company.—On Saturday last the petition for the winding-up of the J. B. Rogers Electric Light and Power Company (Limited) was heard before Sir James Bacon in the Chancery Division of the High Court of Justice. The company was registered in July, 1882, with a capital of £500,000. Mr. Marten, Q.C., and Mr. Swinfen Eady appeared for the petitioner, Mr. J. B. Rogers, who was the patentee, and sold the patent and plant to the company. Mr. Hemming, Q.C., and Mr. Leigh Bernard and Mr. Boome supported the petition. Mr. Millar, Q.C., and Mr. Grosvenor Woods, for the company, opposed the petition on the ground that there was a balance of £350 at the bank, there were the patent and plant, and Mr. Rogers himself in June had represented the company as likely to succeed. Mr. Bramwell Davis, for the holders of 2,225 shares, and for debenture holders to the amount of £13,900 out of £34,000, opposed the the petition. The Vice-Chancellor said the only ground alleged for winding-up the company was that it was short of money; it would be unjust and inequitable to sacrifice the property of the shareholders, and the petition must be dismissed with costs.

The Late Sir William Siemens.—The will of the late Sir William Siemens, F.R.S., &c., was proved on December 29th, 1883, by Mr. Alexander Siemens, Mr. Joseph Gordon-Gordon, and Mr. John Wreford Budd, the executors, the probate being stamped to cover personal estate in the United Kingdom of the gross value of £382,423 12s. 5d. Under the will, which is dated August 21st, 1882, Sir William Siemens gives to his widow, Lady Siemens, certain pecuniary and specific legacies, and an annuity of £4,000, and a life interest in his freehold property, Sherwood, Tunbridge Wells. He gives various pecuniary and specific legacies to relations, friends, his assistants, and others; £2,000 to the German Hospital, Dalston; and £1,000 each to the German Society for Benevolence, the Tunbridge Wells Infirmary, the Scientific Relief Fund of the Royal Society, the Benevolent Fund of the Institution of Civil Engineers, and the Pension Fund of Siemens Brothers and Co. (Limited). There are also legacies to domestic servants who have been five years in his employ. The testator also makes provision by his will for the carrying on, under the same management as during his lifetime, of his civil engineering business, including his patented inventions.

The Health Exhibition.—As we have stated before, it is intended to hold this exhibition in May next. The groups into which the exhibits will be gathered have been made known. These are six in number, viz.:—1, Food; 2, Dress; 3, The Dwelling House; 4, the School; 5, the Workshop; 6, Educational Works and Appliances. Electrical apparatus will no doubt be exhibited under Class 26, Group 3, which includes (*a*) Electrical Apparatus for Illumination and Domestic Use, Secondary Batteries, Electroliers, Accumulators, &c.; (*b*) Apparatus for Lighting by Gas, Gas Producers, Gas Meters, Gas Fittings, Chandeliers, &c.; (*c*) Oil and other Lamps, and Stoves; Mineral Oil, Wax and other Candles, Vegetable and Animal Oils. Also, under Class 51, Group 6, in which will be shown (*a*) Apparatus and Models for Elementary Science Instruction in Schools; Apparatus for Chemistry, Physics, Mechanics, &c.; (*b*) Diagrams, Copies, Text Books, &c.; (*c*) Specimens of the School Work in these subjects. Applications for space should be sent in before the 1st of February on forms to be obtained of the secretary, International Health Exhibition, South Kensington, S.W. The exhibition will open on the 1st May, and remain open for six months or more.

A Slight Mistake.—A voltaic cell caused a great commotion the other day at Windsor. It appears that a stranger arrived at one of the hotels in the royal borough early in the morning, and, having knocked the inhabitants up, engaged a bed room, and forthwith went to bed. He slept till 7 p.m., and then got up, dressed himself, and went out, leaving behind him in the bed room a suspicious-looking parcel. The peculiar hour of his arrival—when ghosts do stalk abroad—his hurried movements and nervous manner aroused suspicion in the breasts of the hotel people. His bed room was searched, the parcel discovered, forthwith opened in the presence of a police superintendent, and found to contain a white earthenware jar, partly filled with lumps of a black substance, much resembling coarse blasting powder, while from the cap which surmounted the jar projected an unearthly-looking wire attached at the underside of the cap to a "flat oblong cake, of a substance like compressed charcoal." There could be no doubt about it, the police were on the track of a ferocious Fenian, and had already possessed themselves of his infernal machine. The police superintendent hurried to the nearest medical man for an opinion on this diabolical-looking piece of apparatus, and was rewarded by being told that it might, when properly charged, ring an electric bell,

Digitized by Google

but the harm it was capable of would be limited to that. We are not told what became of the mysterious stranger, nor the light in which he viewed the matter. Electricians journeying about the country with batteries will do well to keep them from the eyes of the police.

Honour for a Telegraph Engineer.—The Queen has conferred the honour of knighthood upon Colonel Francis John Bolton, C.E., M.S.T.E. and E., &c., who is well known in electrical circles as honorary secretary to the Society of Telegraph Engineers and of Electricians, of which he was an originator. Colonel Sir F. J. Bolton is a son of the late Dr. Thomas Wilson Bolton, surgeon, of London. He was born in 1831, educated at Morden Hall, and received his first commission in the army in 1857. Served in the Gold Coast Artillery with the expedition against the Crobboes in 1858, including the action of the Crobboe Heights on the 18th September, and in the expedition against the Donnquah rebels in 1859, which resulted in the capture of all the rebel chiefs. For his services on the West Coast of Africa he received special thanks, and was promoted captain in the 12th Regiment, 1861. He served on the staff as D.A.Q.M.G., and was attached to the Royal Engineers, 1866-69. In 1868 he obtained his promotion as major (unattached) for special military scientific services. His subsequent promotions were: Lieut.-colonel in 1877, and retired colonel, 1881. He is the inventor of the system of telegraphy and visual signalling which was adopted into Her Majesty's services in 1863. This system now forms part of the Army Organisation, and has been successfully applied on active service in the recent Abyssinian, Indian, African, and Egyptian Wars, and is also adapted generally in India and the colonies. He received the honour of knighthood for his special service to the army. He is a civil engineer, and was appointed the water examiner under the Metropolis Water Act, 1871.

Just Criticism.—We do not as a rule agree with the remarks of our contemporary the *Journal of Gas Lighting*. Perhaps it is hardly to be expected that we should, particularly when it makes mountains out of molehills in its hypercritical endeavours to hold up anything and everything electrical to the scoffs and jeers of the world of gas. This rule, like many others, has its exceptions, and in its remarks upon the withdrawal of the Edison system from the Holborn-viaduct, we cordially agree with our contemporary. We quote these remarks in full. They are as follow:—"The subscribers to the great Edison electric lighting installation on the Holborn-viaduct have received a courteous intimation from the secretary of the United Swan and Edison Company, to the effect that the supply will soon be terminated, and they are therefore requested to inform the company when it will be convenient to have their service cut off. Thus ends the enterprise from which so much was expected, and which has done so little beyond keeping itself in existence at a cost that will never be revealed. Of course it will be said that this stoppage is only a preliminary to a recommencement of operations elsewhere in a more favoured district. But it will occur to most people that the position occupied by the Edison Company on the Viaduct was as good as they can hope to find in any other part of London. It is a central site, on a thoroughfare provided with subways, whence the extension of supply into the most thickly populated and opulent part of the City was extraordinarily convenient. The whole of the City of London was open to the introduction of the incandescent system from this centre of supply. Wherefore, then, retreat with the road to victory clear? The company's circular states that the installation was intended to prove the scientific possibility of supplying incandescent lighting; and this having been done — the lighting is to cease at the earliest possible date! Truly a curious method of signalising a triumph. The subscribers who went to considerable expense to adapt their interior fittings for the Edison system will, of course, lose their money, which will constitute their reward for the enterprising spirit they displayed, and the patience with which they endured the occasional eccentricities of the light. Their fate will scarcely be an encouragement to the subjects of the next attempt on the part of the United Company."

Sir Wm. Thomson on Electrical Measurements.—At a recent meeting of the Glasgow Philosophical Society Dr. Henry Muirhead presiding, Sir William Thomson read a paper on "The Measurement of Electric Currents and Potentials." The subject he said, was one of great practical importance to electricians at the present day. The measurement of electrical quantities in definite units became a practical subject in connection with telegraphy, and it was a remarkable and interesting fact, and one which those engaged in practical electricity might take some pleasure in contemplating, that the practical work had now reacted on the laboratories. Whereas before 1865 there had been scarcely such a thing as definite measurements of electrical currents and potentials in scientific laboratories, the growth of telegraphy had brought out the imperative necessity for a system of measurements in some definite units, and the practical applications of electricity had come on so very rapidly that they had outrun the capacity of scientific measures to give definite and accurate measurements. He had been greatly impressed at the Electrical Exhibition in Vienna with the want of instruments of measurement which could be both definite and approximately accurate. Before long, however, they would probably have instruments that would give the measured results with almost unerring accuracy up to a certain percentage. He himself had laboured very much to try and gain some slight improvement in some parts of the large field of electrical measurement, and that evening he wished to bring before them some instruments, and also some suggestions as to future instruments, which seemed to him of some importance, not only in laboratories, but also in practical applications of electricity as they were developing at the present time. The galvanometer was in one form or another the foundation of the instruments then before them; but there was another form of instrument—the electrometer—which was destined to play an important part in the application of electrical measurements. Sir William then explained at great length two instruments of his own invention—namely, a graded current meter for measuring currents of electricity, and a graded potential meter for measuring electromotive force. In the case of the latter, he showed the method of adjusting the instrument so that its indications should correspond to round numbers of electromotive force. He also illustrated the lecture by exhibiting and referring to Siemens's electro-dynamometer and Siemens's watt meter. In the course of the evening, Sir William mentioned that in future he should express the measurement of the rate of conductivity by "mhos," a term which, he thought, would be useful in describing the reciprocal of "ohms," by which the rate of resistance was expressed. Sir William afterwards, in a second paper, alluded to measurements made by Mr. Abdank and himself in the Vienna Electric Exhibition on the current yielded by the new voltaic element of Lalande. The battery, he said, was superior to that of Bennet. It had the advantage of settling down in a few seconds of time, and emitted a steady current.

Electric Lighting of Ships.—The ss. "Adriatic," of the

Digitized by Google

White Star Line, is now added to the long list of vessels fitted with the electric light. This list includes in all about sixty ships, of which nearly two-thirds have been fitted by the Edison and Swan Companies, and the remainder with hardly an exception have been fitted with Swan lamps. The "Adriatic" has been in some respects an exceptional contract; for, contrary to common experience, the contractors were not in any way tied down, but were allowed to do the work in the way they thought best, and to use the plant they considered most suitable. The result has been in every way highly satisfactory, for from the time the lights were started for trial on Tuesday morning till the ship was last heard of at Queenstown on Friday week, there had virtually been no stoppage, and a continuous run of about 100 hours with new engines and machines, we think, speaks for itself. The dynamo machines are in duplicate. Each machine is driven by a pair of coupled vertical engines, and is of sufficient capacity to light the whole ship. Each engine of each pair is capable when under main boiler steam with the condenser of driving at least 80 per cent. of the lights, thus giving a large margin of power under ordinary conditions, and enough to do the work when the donkey boiler only is used. At the trial last week the experiment was made of suddenly cutting off 50 per cent. of lights, with the result that the speed of the engines and machines only increased in consequence about 3 per cent., which was not sufficient to produce any noticeable difference in the brilliancy of the lamps. The lamps are of the newest Swan type of 56 volts, and are about 280 in number, partly of 12 and partly of 20 candle-power, all wired in multiple arc. The wiring has been so arranged that the main groups of lights, can all be controlled from the dynamo room, but this arrangement will only be used in cases of emergency, the ordinary working being that each light, or small group of lights, can be lit or put out at any hour of the twenty-four. The wires are all run in wood casings, and each wire has its separate groove. The fittings, holder, switches, cut-outs, &c., are all of the newest patterns. Many of the fittings have been made so as to admit of their being put up or taken down by inexperienced hands at a moment's notice. Several of them are portable, and in a large number of cases they are practically water tight. The engines were built by Messrs. Marshall, Sons, and Co., of Gainsborough, who have spared no pains to make them perfect. They are connected to the dynamos by a continuous rope, working in a grooved fly-wheel and pulley. A sliding-frame bed plate has been used, so that the rope can, if necessary, be tightened while running. The machines are of Messrs. Siemens Bros.' alternating type, this contract having been obtained by the Swan Company before amalgamation with the Edison Company. The work has been carried out by Mr. A. B. Blackburn under Mr. J. F. Albright, who is now in charge of all the shipwork of the Edison and Swan Company. In carrying out the work the contractors were afforded every facility by the engineer of the White Star Line, and it is largely owing to this that it has been possible to ensure such a complete success.

The Proposed Electric Railways in London.—One of the two electric railways which have lately been agitating the public mind, or a portion of it, of late has died a natural death whilst in a very embryonic stage. We refer to the Mid-London Electric Railway which was to have been constructed from Oxford-street to Cornhill. The promoters of this scheme having failed to make the deposit of money required by the standing orders cannot proceed further with their provisional order, and consequently the inhabitants of Oxford-street may apply the money which was to be subscribed for the purpose of opposing this scheme to other purposes. The other line which it is proposed to construct is the London Central Electric Railway. A large portion of this line will run through the district of the Holborn Board of Works, and the following extract from a report recently laid before that board by Mr. Isaacs, their surveyor, is interesting. He says:—The London Central Electric Railway Company seek for powers to construct a railway, to proceed by a junction with the line authorised by the Charing-cross and Waterloo Railway Act, 1882, from its terminus in Northumberland-avenue, to Piccadilly-circus, and from thence, passing under the new street, now in course of formation by the Metropolitan Board of Works, to New Oxford-street, and by way of Holborn, Charterhouse-street, Snow-hill, and Newgate-street to the General Post Office in St. Martin's-le-Grand. The line will be in tunnel for its entire length, and no alteration is intended to be made in the level or gradient of any street or road under which the railway proposes to pass. At Dean-street, Holborn, the upper surface of the rails will be 30 feet below the level of the street, at Red Lion-street 32 feet, at Brownlow-street 27 feet 6 inches, and at the corner of Gray's Inn-road, where doubtless there will be a station, the rails would be 34 feet below the surface of the road; at Hatton-garden the rails would be 32 feet, and in Farringdon-road 16 feet 5 inches below the level of the road. The tunnel itself would be 10 feet in height. It will thus be seen that in the Farringdon-road there would only be 6 feet 5 inches between the crown of the tunnel and the surface of the road, so that, if it were required to lay down at any future time a trunk gas main, such as has been recently placed by the Chartered Gaslight Company in the Clerkenwell and Theobald's roads, it would be impossible to do so. The level of the railway at this particular part of its route would seriously interfere with such an user of the road by any gas or water company. The gradients of the line are exceedingly good, there being none within the Holborn district more severe than an inclination of one in fifty-two. The proposed railway would be a great boon to Londoners generally; worked by electricity (if electricity can be relied on as a motor) (*sic.*), the tunnel would be free from the mephitic vapours, which tend so much to destroy the comfort of those using the underground railways as at present worked by steam. With all the engineering skill that could be brought to bear in the execution of the works, allowing that a great portion would be executed in tunnel, shafts must be sunk at convenient distances to admit of the excavation being brought to the surface, and the materials for the formation of the tunnel being sent below. It would be idle, therefore, on the part of the promoters to contend that such operations could be conducted without serious inconvenience and loss to the occupiers of the premises along the line of route, and they, no doubt, will expect that the public bodies entrusted with watching this measure through Parliament will obtain for them some compensation.

Overhead Wires in Wandsworth.—On Monday Mr. Paget (the stipendiary magistrate of the Wandsworth Police Court), the arbitrator appointed under the Telegraph Act, 1878, held by adjournment a sitting at the Law Institution, to determine the difference which has arisen between the Postmaster-General and the Wandsworth District Board of Works, with regard to certain overhead wires in its district, as mentioned in previous notes. Mr. Casserley, barrister, instructed by Mr. Goss, from the Solicitor's Department of the General Post Office, appeared for the Postmaster-General; and the Wandsworth District Board of Works was repre-

Digitized by Google

sented by Mr. Corsellis, their clerk.—The wires in question are to form fire alarm circuits for Putney, Wandsworth, Battersea, Clapham, and Tooting—all within the jurisdiction of the Wandsworth Board. The first of the proposed circuits inquired into was one which would connect the police station at Wandsworth with the police station at Putney. Two wires required to work this circuit have already been erected without any consent having been given by the Board, but it was agreed that the matter should be considered as if they had not been erected.—Mr. Henry Eaton, the superintending engineer of the Metropolitan Postal Telegraphs, stated that the wires in question crossed the Upper Richmond-road, but no other public road. The span was about thirty yards in length, and supposing consent were given by the Board, the cost would be about 20s., but if consent were not given the wires would have to be laid underground at a cost of from £13 to £14. The consent of the owner of the house, on which there was an attachment, had been obtained.—Mr. Radford, surveyor of the parish of Putney, estimated the cost of breaking up the road and of a private passage so as to make the connection with the wire on the railway embankment at only £1 2s. The next circuit which was brought under notice was called the Battersea circuit, in which it is proposed to erect two additional wires from the Battersea Fire Brigade Station, Orkney-street, to Lavender-hill, there to be connected with the underground wires. The wires will cross Warsell-street.—In cross-examination by Mr. Corsellis, as to this circuit, Mr. Eaton stated that there is an underground circuit with twenty-five wires from London up the Wandsworth-road to Clapham Junction, but that line was a main line, intended to serve the provinces, and not the district. Putting an additional wire overhead would cost £8 a mile for each wire, but to place the wires underground would cost something like £350 per mile. That was the lowest sum, the contracts being generally at from £350 to £500 per mile. In cross-examination by Mr. Corsellis, the witness said he had never admitted that there was danger in overhead wires, but there was apprehension.—Mr. Bilditch stated that the wires would cross twenty-six public roads.—The next circuit brought before the attention of the arbitrator was the Wandsworth circuit, in which it is proposed to connect the old police-station at Wandsworth with the new, and the new with the wires on the South Western Railway at Love-lane; but in reference to this Mr. Eaton said that some consents of owners of houses to which the lines now in existence are attached had been withdrawn, and that it might become a question, if a number of wires had to be laid, whether it would not be more economical to lay them underground, and it was agreed that the question as to this extension should be postponed, and some further evidence having been taken as to a proposed extension from the Wandsworth Railway Station to the Wandsworth Fire Brigade Station, which would be an entirely new line, the inquiry was adjourned until yesterday (Friday).

United Telephone Company v. Dale.—This was a motion, on behalf of the plaintiffs, that the defendants, Henry James Dale and Edward Dale, might be committed to prison for contempt of court in manufacturing, selling, and using "carbon transmitters," manufactured according to the manner described in certain letters patent dated the 30th of July, 1877 (Edison's patent); and also in manufacturing, selling, and using "telephone transmitters and receivers" manufactured according to the manner described in certain letters patent dated the 9th December, 1876 (Bell's patent), in disobedience of the judgment delivered in the action on the 1st of February, 1883. It came before Mr. Justice Pearson on Monday last. Mr. Cozens-Hardy, Q.C., and Mr. Moulton appeared for the plaintiffs; Mr. Higgins, Q.C., and Mr. Farwell for the defendants.—His lordship said that the action was commenced in January, 1883; on the 23rd of January, 1883, the defendants were so convinced that they had no defence that they wrote a letter unconditionally consenting to an injunction as to one part, and on the 1st of February they consented to a perpetual injunction as to both parts of the injunction asked for. There could be no mistake, then, on the part of the defendants as to what was the subject matter of those parts, or what was the exact infringement complained of. There had been a very flagrant and disgraceful breach of the injunction. It was admitted that in July, 1883, they had fitted up certain apparatus for Messrs. Farmiloe; that when challenged with this in September they wrote to the company, telling them that that was the only case in which they had violated the terms of the injunction, and that the company could inspect their books at any time. Now, it appeared that, after the injunction was granted, they were actually sending this very apparatus to Mr. Tidman for sale, and stating that they sent him no invoice with it because (as Mr. Tidman understood) they wished to avoid any entries in their books relating to it. Of course if they were to enter these sales in their books, the books would at once show that the injunction had been broken. They were, therefore, attempting, secretly and in fraud, to obtain an advantage which by the injunction they were restrained from getting. Fortunately, for the sake of justice, their letters remained to convict them; and they convicted them so clearly that it was impossible to offer any defence to this motion. But a preliminary objection was taken that the injunction had never been served upon the defendants; and the rule relied upon was that in no case where, as here, there had been sufficient time to draw up, enter, and serve the order, would the Court make an order to commit to prison without actual service of the injunction upon the defendants. His lordship, however, declined to act upon the rule that the Court would in no case enforce its order by committal simply because the order had not been served, when it appeared beyond all doubt that the defendant was aware that the injunction had been granted, and of the intention of plaintiff to enforce the order. Here, under the circumstances, the service of the order was unnecessary. There had been a most discreditable breach of the injunction, and the Court would be declining from the duty which it owed to the public if it did not order that these defendants should be committed to prison. Henry Dale had said that his brother Edward knew nothing about the matter complained of, but Edward Dale had made no affidavit, and it seemed inconceivable that he did not know of them. His lordship, therefore, could make no distinction between the brothers. There must be an order for their committal to prison, and they must pay the costs of the motion. —On the day after the above judgment had been given and an order made for the committal to prison of both the defendants, Mr. Higgins, Q.C., made application on behalf of Edward Dale that he might be exempted from the order on the ground that he knew nothing whatever of the circumstances connected with the breach of injunction. It appeared from affidavits made by each of the defendants that Edward Dale was by profession a conjuror, and only nominally a partner in his brother's business, and was not in any way acquainted with the transactions in which the firm was engaged.—Mr. Justice Pearson said that under the circumstances he would exempt Edward Dale from the order for committal to prison, but he could not exempt him from the order for payment of costs.

## ELECTRO-CHEMISTRY.

### INORGANIC.

BY DR. G. GORE, F.R.S.

(CONTINUED FROM PAGE 199.)

**Electrolysis of Aqueous Hydrofluoric Acid.**—According to Faraday, aqueous hydrofluoric acid is not decomposed by electrolysis, but only the water in it. I electrolysed the pure dilute liquid containing about 10 per cent. of the acid, by means of a separate current and sheet platinum electrodes. Gas was evolved freely from each electrode, and a very strong odour of ozone was observed. No corrosion of either electrode occurred during twelve hours action. The gas from the anode was collected; it re-inflamed a red hot splint vividly; paper wetted with spirits of turpentine was not blackened, nor was bright silver tarnished by it; it was oxygen. I similarly electrolysed, by a current from ten Smee cells, the pure aqueous acid containing about 80 per cent. of the anhydrous substance. Copious conduction took place, with much evolution of oxygen at the anode. Heat was produced in the liquid; the anode dissolved slowly; in three hours it lost 1·58 grain. The smell of ozone disappeared if the electric current was much weakened, and reappeared on first contact. In a further eleven hours, the anode lost 5·05 grains, and was covered with a blackish crust which was partly soluble in water to a brownish solution. In a further twenty-hours the loss had increased from 5·05 to 15·00 grains, without any signs of metallic deposit upon the cathode.

I also electrolysed during five hours a chilled mixture of 160 grains of the anhydrous acid, 244·4 grains of concentrated nitric acid, and 273·8 grains of pure water, by means of sheet platinum electrodes and six Smee elements. Free conduction occurred, and much odourless oxygen was evolved. The anode was not corroded, and no gas was visible at the cathode. By similar electrolysis with a current from ten Smee cells of a mixture of equal volumes of 30 per cent. pure aqueous hydrofluoric acid and strong hydrochloric acid, much chlorine was set free from the anode, and hydrogen from the cathode. This is consistent with the usual effect that chlorides, like oxides, are decomposed before fluorides. A mixture of equal volumes of the aqueous acid and strong oil of vitriol yielded much oxygen and a strong odour of ozone at the anode, and hydrogen freely at the cathode. The anode corroded very slowly, and fumes were evolved which rapidly blackened gutta percha. With selenious acid in place of the sulphuric, gas was set free at both electrodes, and much red selenium was deposited upon the cathode. No odour of ozone was evolved until a large quantity of red and black selenium had been deposited; it was then evolved freely. The anode was not corroded during twenty-eight hours free electrolysis. By electrolysis of the dilute hydrofluoric acid, to which some phosphoric anhydride had been added, ozone was evolved from the anode, and hydrogen from the cathode; the anode was also slowly corroded.

Bartoli and Papasogli have also electrolysed aqueous hydrofluoric acid with anodes of wood charcoal or gas-carbon, and found the anodes disintegrate. (*Electrician*, Vol. XI., pp. 28 and 101; *Jour. Chem. Soc.*, Vol. XLIV., 1883, p. 599.)

**Separation of Chlorine.**—Cl. Electro-chemical equivalent = 35·5. A monad anion. Set free on passing, by means of an anode of carbon or platinum, an electric current through concentrated hydrochloric acid, or through aqueous solutions of the chlorides of sodium, ammonium, or other metals, also through various chlorides in a state of fusion. With aqueous solutions, some of the chlorine usually dissolves in the liquid. The electrolyses of chlorine water yields hydrochloric acid at the cathode, and a little chloric acid at the anode. (Balard, also Connell, Gmelin's "Handbook of Chemistry," Vol. I., p. 451.)

**Electrolysis of Hydrochloric Acid.**—H Cl. Molecular weight = 36·5. I ascertained by experiment (*Proc. Roy. Soc.*, May 4, 1865) that the anhydrous substance, liquefied by great pressure, is a very feeble conductor of electricity. Two fine platinum wires immersed in it $\frac{3}{8}$ths of an inch in length and $\frac{1}{10}$th of an inch asunder, and connected with ten Smee elements, evolved no perceptible bubbles of gas, and produced only a small deflection, amounting to 23° of the needles of a sensitive galvanometer; and this amount of conductivity might possibly have been due to a minute trace of oil of vitroil mixed with the liquid acid. In a second similar experiment, with the wires $\frac{1}{10}$th of an inch apart, not the slightest conduction occurred on using the same battery power, but by employing the secondary current of a strong induction coil, with condenser attached, conduction and a steady deflection of 20° of the needles took place, gas being freely evolved from the negative wire only. It is evident, therefore, that liquefied hydrochloric acid is a very bad conductor of electricity. Bleekrode subsequently discovered (*Proc. Roy. Soc.*, Vol. XXV., 1876, p. 325) that the anhydrous liquefied acid "opposes a formidable resistance, and is not decomposed in a perceptible way" by the passage through it of a current from 5,640 cells of De la Rue's chloride of silver battery.

Gallium liberates hydrogen freely by simple immersion in dilute hydrochloric acid (M. Lecocq de Boisbaudran).

Electrolysis of concentrated hydrochloric acid with a platinum anode causes the anode to dissolve, but that of the dilute acid causes the formation of chlorine compounds at the anode without corroding the platinum (D. Tommasi, *Jour. Chem. Soc.*, Vol. XLIV., 1883, p. 142).

In dilute solutions of metallic chlorides by electrolysis hypochlorous acid is alone produced; in concentrated ones chlorine is also set free. Chlorates are produced from the chlorides of the alkalies and alkaline earths, as soon as the reaction of the solutions has become alkaline, from the evolution of the chlorine and hypochlorous acid (C. Luckow, *Jour. Chem. Soc.*, Vol. XXXVIII., 1880, p. 282). If dilute chloride solutions contain a little free hydrochloric acid, hypochlorous acid is alone produced, and the solution, after a time, acquires an alkaline reaction.

The electrolysis of aqueous solutions of certain metallic chlorides by means of the contact of two metals has been investigated by Gladstone and Tribe (*Phil. Mag.* [4], Vol. XLIX., p. 425), and will be described under the headings of the respective metals. Thorpe has shown that the copper zinc couple reduces chlorate of potassium to chloride (Gladstone and Tribe, *Jour. Chem. Soc.*, Vol. XXXIII., 1878, p. 147). Platinum charged with hydrogen behaves similarly (*Ibid.*, p. 309), but more powerfully.

**Electrolysis of Oxides of Chlorine.**—Very little has been done in this part of the subject. Aqueous solution of oxide of chlorine ($Cl\ O_2$) yields hydrogen at the cathode and a small quantity of oxygen gas and perchloric acid at the anode (Count Stadion). I have electrolysed aqueous chloric and perchloric acids with anodes of silver.

**Separation of Bromine.**—Br. Electro-chemical equivalent = 80. A monad anion. It is separated in many cases when aqueous solutions of bromides are electrolysed by means of a separate current and an incorrodible anode. A portion of the liberated bromine usually dissolves in the liquid, an aqueous solution of bromine yields by electrolysis hydrobromic acid, and a mere trace of hydrogen at the cathode, but no bromic acid at the anode. The water is decomposed (Balard, also Connell, Gmelin's "Handbook of Chemistry," Vol. I., p. 451).

**Electrolysis of Hydrobromic Acid.**—HBr. Molecular weight = 81. Bleekrode has stated (*Proc. Roy. Soc.*, Vol. XXV., p. 323) that anhydrous hydrobromic acid is a non-conductor to the voltaic current from eighty Bunsen elements. The aqueous acid when electrolysed by a separate current liberates bromine at the anode, and hydrogen at the cathode.

**Electrolysis of Oxides of Bromine.**—I have been unable to find any record of any one having electrolysed either bromic or perbromic acids, or aqueous solutions of their salts. By immersing a sheet of aluminium in an aqueous solution of bromic acid, I observed that hydrogen and bromine were set free,

Digitized by Google

**Separation of Iodine.**—I. Electro-chemical equivalent = 127. A monad anion. It is, however, sometimes separated by secondary action at the cathode. According to Bleekrode (*Ibid.*) liquid anhydrous hydriodic acid does not transmit any current from eighty Bunsen elements. Faraday observed that by electrolysis, with a separate current, of potassic iodide, or iodide of lead, in a state of fusion, iodine was set free at the anode. A solution of iodine in water yields by electrolysis some hydrogen at the cathode. The water is decomposed (Balard, also Connell, Gmelins's "Handbook of Chemistry," Vol. I., p. 451.).

**Electrolysis of Aqueous Hydriodic Acid.**—A concentrated solution of aqueous hydriodic acid yields by a separate current, and platinum electrodes, iodine alone at the anode; but a dilute one yields iodine and oxygen (Faraday). Matteucci observed that the stronger the current, and the more dilute the acid, the greater was the proportion of oxygen.

If the solution of an iodide be covered with starch jelly, the cathode be placed in the former, and the anode in the latter, the starch is turned blue around the anode, even if the solution contain a much larger quantity of bromide or chloride than of iodide (Steinberg, *Jour. Pr. Chem.*, Vol. XXV., p. 288, Watts's "Dictionary of Chemistry," Vol. III., p. 287.

Riche states (*Comptes Rendus*, Vol. XLVI., p. 348) that iodic acid ($HIO_3$) is produced by electrolysis of aqueous iodine, or an aqueous solution of hydriodic acid. In the latter case the acid is simply oxidised to iodic acid by oxygen evolved by the decomposition of water. In the former case the iodine is first converted into hydriodic acid, and then oxidised in this way.

## EVOLUTION OF DYNAMO MACHINES.—V.

BY JOHN T. SPRAGUE.

(CONTINUED FROM PAGE 178.)

44. The series and the shunt machines, while regulating the current to a considerable and useful extent, do not accomplish this with the perfection or with the instant action which is required in electric lighting, as in this application of the current very small variations produce great effects, because the light varies in a very much higher ratio than the variation of current. The evil effects of any variation are therefore much greater than those in electro-metallurgy, considered in Section 42.

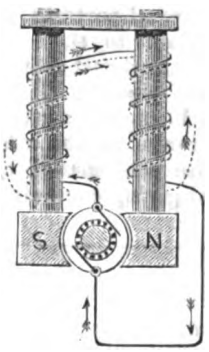

FIG. 23.—Combination of Self-Excited and Separately Excited Fields in a Series Machine.

45. Let us assume, for convenience of figures, that the full work is 100 lamps in multiple arc, each of 100 ohms, and requiring 1 ampere current. This gives a total R of 2 ohms, assuming machine and work to be equal, and an E.M.F. of 200 volts. When all are turned off but one lamp there would be a current of 2 amperes going through it; this not only means heating the carbon to four times its proper temperature, but the light would suddenly flash up from 20 to 160 candles, and the lamp would probably be destroyed. orresponding results occur with incandescent or arc lamps in series; so that the old electrical conditions do not apply when we come to deal with a number of irregular actions which cannot be controlled.

46. What is really required to make the conditions analogous to those in batteries is a mode of adding a fresh battery, that is to say, an additional E.M.F. in multiple arc or in series at the same instant that the additional work is inserted in the circuit in those orders. In other words, for actions in multiple arc we need a *current varying with the work*, and an *E.M.F. constant at the work*. For action in series we need an *E.M.F. varying with the work*, and a *constant current through the work*. These varying capabilities have been developed in the dynamo machine.

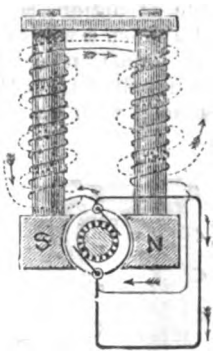

FIG. 24.—Combination of Self-Excited and Separately Excited Fields in a Shunt Machine.

47. A step in this order of evolution is shown by Deprez's system of combining the separately excited with the self-exciting field, shown by Fig. 23 on the series system, in Fig. 24 on the shunt plan.

The first of these produces constant E.M.F., and the second constant current, but the process is so complicated, and the same result can be attained so much more simply, that it is only necessary to indicate this as a stage of development.

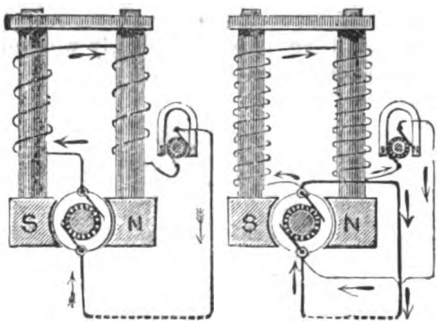

FIG. 25. FIG. 26.

Fig. 25.—Method of Exciting Series Machine by a Permanent Magneto Machine.

Fig. 26.—Method of Exciting Shunt Machine by a Permanent Magneto Machine.

48. The same remark applies to the plan proposed by Professors Ayrton and Perry, which furthermore is distinguishable from Deprez's by the combination of a permanent magneto machine, the current from which, in the series form (Fig. 25), is passed through the whole circuit instead of being confined to the field magnet. Fig. 26 shows the shunt system, in which the current of the magneto passes through the armature of the principal machine. It is obvious that these systems of combined self and external action consist of a modification of the mode of connecting the two circuits of the early Wilde machine, the object aimed at being to secure a constant E.M.F. in portions of the circuit, independent of the varying conditions, and so balanced that the varying conditions of the circuit itself introduce the necessary compensating variations in the E.M.F. of the whole circuit.

49. A combination of the shunt and series machines was employed in what may be called the early days of the dynamo, though in actual time only a very few years ago.

Digitized by Google

The object, as in the case of the so-called "teazer" of the Brush machine, was to secure a minimum field magnetism independent of the current passing in the external circuit, and in series through the field. At this stage, this independent shunt circuit, always fed from the armature, was simply a wire of high resistance, just capable of producing the minimum or initial magnetism, or in reality to supplement the principle of accumulation from the mere residuary magnetism of the iron itself. But evolution means both the development of new organs and the cultivation of new functions by modifying existing organs, and as the process is one of small changes and selection of the fittest results, and as in Section 48 we saw the mere change of connections result in a different principle of action, so the perfecting of the dynamo, and giving it almost a will of its own, in the sense of a capacity to regulate its action according to the requirements of its work, has resulted from the combination of the shunt and series systems, with an exact proportioning of their influence.

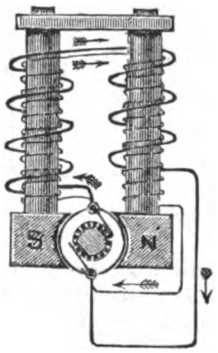

FIG. 27.—Combination of Shunt and Series System.

50. Fig. 27 shows the combination in its simplest form, while Fig. 28 is an arrangement suggested under the name of "series and long shunt," by Professor Silvanus Thompson, from whose Cantor Lectures I have taken the drawings of the various systems of field magnets. The compound system of Fig. 27 is applied in various modes to several dynamos, but has been most completely worked out in the Crompton-Kapp compound Bürgin.

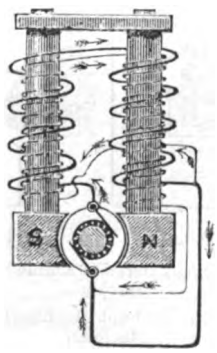

FIG. 28.—Series and Long Shunt Arrangement.

51. As shown Section 45, it is of supreme importance in electric lighting that the current should be absolutely uniform at all times in each individual part of the work, and unaffected by changes made in other parts. That is to say, each lamp requires a fixed current to work it; the lighting up of other lamps must not deprive it of any of its current; the sudden turning off of a number of other lamps must not send such excess of current into it as to press it beyond its powers of endurance, which might destroy it; nor should there be any noticeable fluctuation in its light. These same problems have to be dealt with in the case of gas lighting, though in this the evil is only the roaring of the burner and some waste of gas. Still, with gas, as in the electric light, a constant current is required, with varying external pressures. An automatic control effects this in the form of the governor, which diminishes or increases the passage of gas inversely with the varying pressure.

52. When a governor is not used, some one has to attend to the gas tap; and a corresponding control was used at first in the case of electricity, an attendant, with a standard lamp under constant inspection, introducing or removing resistances, increasing or diminishing the field strength, as this light fluctuated. But this of necessity means *the correction of an evil after it is produced.* This is so even when a governor, actuated by the varying current, is made to introduce the compensations automatically, while it is desirable rather to *prevent the evil from occuring,* or at all events to meet it in the very initiatory stage before its consequences become observable.

53. In an externally excited field system the *electromotive force* generated in the armature is nearly constant for a given speed of rotation, no matter what changes are made in the circuit (Sections 32, 33). But this uniform E.M.F. will not generate uniform current, or even uniform ratio of current, in external work, because there is a constant element of resistance in the armature itself, which changes its ratio to a variable external circuit. What is wanted is a constant E.M.F. at each point in the external circuit. As the "fall of potential," or the ratio of E.M.F. consumed, which also means energy expended in different parts of any circuit, is proportional to the resistances of the several parts, it follows that we require the armature to generate, not a constant E.M.F., but an E.M.F. varying with the resistances.

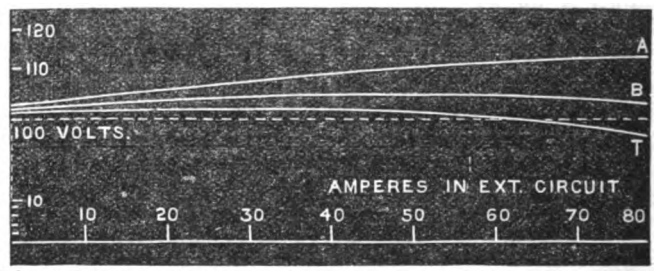

FIG. 29.—Characteristic Curve of a Crompton-Bürgin Compound Dynamo.

54. This involves a consideration of the relations of the several parts of the circuit, and of the E.M.F. necessarily expended in each separate part, and an examination of the "characteristic curves" produced in different circumstances. In fact, the *curve* of the external work should be a perfectly straight horizontal line in an ideally perfect machine. Fig. 29 shows the characteristics of a compound Bürgin on the Crompton-Kapp system.

The vertical scale is that of E.M.F., and the horizontal scale that of amperes of current delivered in the external circuit. The curves, therefore, show the E.M.F. generated, and available in the several portions. A is the curve of the armature with forces rising to the requirements of the total circuit; B is that at the brushes which supply the field-magnets and external circuit; T is that of the terminal screws, which should be nearly a straight line, representing a constant E.M.F. through all the ranges of current called for, which in this case was that of a machine running at 1,600 revolutions, and giving currents from 2 to 80 amperes.

## ON MECHANICAL DYNAMOMETERS.

BY GISBERT KAPP.

(CONTINUED FROM PAGE 152.)

*Transmission Dynamometers.*

The oldest and perhaps highest authority on dynamometers is General Morin, who in 1841 published a paper, "Notice sur divers Appareils Dynamométriques," dealing especially with transmission dynamometers. General Morin's apparatus has even at the present day considerable interest, since many instruments now in use are based upon or only modifications of his and Poncelet's inventions. His rotary dynamometer consisted of a shaft driven by the prime mover and a pulley, loose on that shaft, from which a belt conveyed the power to the machine to be tested.

The pulley, although not keyed to the shaft, was not quite

Digitized by Google

free, but connected to it by means of one or more straight radial springs set in a boss, which latter was keyed on to the shaft. These springs were deflected proportionately to the twisting couple transmitted, and thus the pulley lagged behind the shaft when transmitting power. If the springs are not overstrained the amount of lag is proportional to the twisting moment. To the shaft was rigidly fixed a framework placed radially, and carrying a set of rollers wound with a paper band, and to the rim of the pulley was fixed a pencil set to touch the paper. If the paper rolls be revolved and the springs are not deflected, a zero or datum line would be drawn on the paper band parallel to its edges. But if at the same time the paper is moved with a speed corresponding to the angular velocity of the shaft there is a strain, and consequently a deflection in the springs, then a curve would be drawn on the paper, and the area enclosed by this curve and the zero line would be proportional to the mechanical energy transmitted. In this way Morin's dynamometer was a true integrating instrument. The speed of the paper was made proportional to the angular velocity of the shaft by the simple device of a pair of bevel wheels, one of which was connected by a worm and wheel to the paper rolls and revolved with the framework, whilst the other surrounded the shaft and was held stationary. The bevel wheel mounted on the framework rolled, so to say, on the fixed bevel wheel, and therefore the velocity of the paper was proportional to the speed of the shaft.

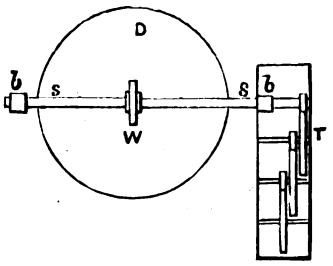

FIG. 18.—Integrating Wheel.

Before describing any of the modern and improved forms of Morin's dynamometer, a few remarks must be made on the question of integrating the energy transmitted during a given time. Morin's original method of letting the apparatus itself draw a curve, the abscissæ of which correspond to revolutions of dynamometer shaft and the ordinates to torque transmitted, has the advantage of showing (like a steam engine diagram) the process of transmission in all its stages, and leaving a graphic record for future reference. But, if we do not care to know and record all the minute variations in the power, and only ask for the total energy transmitted during a given time, the paper band and pencil can be replaced by the simpler device of an integrating wheel.

To explain its action, let in Fig. 18. D be a flat smooth metal disc provided on its under side with a spindle and suitable gearing by which it can be revolved with a speed proportional to that of the dynamometer.

A light spindle, *s s*, free to revolve, but otherwise held in bearings, *b b*, is laid parallel to a diameter, and across the face of the disc at such a distance that the small integrating wheel W mounted on this spindle just touches the face with gentle pressure. The wheel can slide, but not turn on the spindle, and its position longways is controlled by a fork (not shown in the diagram). Imagine this fork connected with the springs of the dynamometer in such a manner that the deflection of the springs results in a proportional displacement of the wheel along its spindle, and assume further that the wheel stands exactly in the centre of the disc when there is no strain in the springs, then the distance of the wheel from the centre of the disc is at all times a measure for the torque in the dynamometer.

Since the springs revolve and the fork does not, the connection between the two must be such as to admit of this relative movement without impairing in any way the principle that the position of the fork corresponds to the deflection of the spring.

From the foregoing description it will be evident that whenever the integrating wheel leaves its central position it begins to revolve, rolling as it were upon the face of the disc which is travelling under it.

Let $r$ be the distance to which the fork has been pushed from the centre by the deflection of the springs and $\omega$ the angular velocity of the disc, then the speed of the rim of the integrating wheel is $\omega r$, and the number of revolutions it imparts to the spindle *s s* during a given time, $t$, will be proportional to $t \omega r$. Since the disc is geared with the dynamometer shaft, the speed of the latter is proportional to $\omega$; and since $r$ is proportional to the torque transmitted, the product $\omega r$ is proportional to the energy transmitted by the dynamometer in unit time. Let the spindle *s s* be connected to a train of clockwork T, which for convenience might be geared in the proportions 1, 10, 100, 1,000, and observe the positions of the four pointers at the beginning and at the end of time $t$. If during this period the counter shows $n$ revolutions, the total energy transmitted is $a n$, where $a$ is a co-efficient depending on the dimensions of the different parts, strength of springs, ratio of gearing, &c., and the energy transmitted per unit time, or what is commonly called, the horse-power is

$$\text{H.P.} = a \frac{n}{t}.$$

The rim of the integrating wheel is rounded so as to have a definite point of contact on the face of the disc. Its movement being partly rolling and partly sliding the diameter of this wheel is liable to be lessened by constant use. At the same time the springs of the dynamometer may alter in consequence of the strains put upon them, and hence the co-efficient $a$ should from time to time be redetermined by actual experiment, as shown by Mr. Rich in his paper read before the Institution of Mechanical Engineers, *Proceedings*, July, 1876. In this paper the application of the integrating disc to traction dynamometers and their calibration are given in full, but need not be entered upon here, as being outside electrical enigneering. The data and illustrations on rotary dynamometers in Mr. Rich's paper come, however, more directly within the scope of these articles, and where made use of are marked with an asterisk. Apart from the sources of error mentioned above there is the tendency of the radial springs in Morin's dynamometer to straighten themselves in consequence of centrifugal force, and thus the dynamometer will indicate less power than is actually flowing through it.

The error due to this course becomes important when testing high speed machinery like dynamos, but, as will be shown presently, it can be eliminated by replacing the original straight radial springs by a double set of springs coiled in opposite directions.

Before describing any of the modern forms of Morin's rotary dynamometer, a modification of it, designed by M. Saurin for the testing of marine engines, should briefly be mentioned. The apparatus is interesting because able to deal with large powers. If a straight spring of uniform section be held rigidly at one end, and the deflecting force applied at its free end in a direction perpendicular to its length (similar to the load on a cantilever), then a minimum of force will produce a maximum deflection. If both ends are supported and the load applied in the middle, the deflection will only be one quarter of what it was before. Or, for the same weight of steel employed and with an equal deflection, the force to be measured can be quadrupled. This arrangement will, therefore, be better than Morin's original plan of straight radial springs if large powers are to be transmitted. But M. Saurin goes a step farther. He employs springs slightly curved, and applies the power in such direction as to pull the ends apart and thus straighten the springs. With this arrangement a minimum weight of steel can register a maximum pull at a moderate deflection, as indicated by the more or less complete straightening of the bent springs.

In applying this principle to the measurement of the power flowing from the marine engine into the propeller the

Digitized by Google

shaft is cut, and the ends are connected by an elastic dynamometer coupling, consisting of two crossbars and two bent springs. The crossbars have their centres enlarged to bosses, by which they are keyed to their respective shafts; one to the back end of the engine shaft, the other to the front end of the propeller shaft. The ends or tips of these crossbars are provided with stout pins projecting towards each other, for the attachment of the ends of the springs which are hinged on these pins.

The springs are concave to the shaft, their middle portions being farther from the centre than their ends, and the effect of a pull transmitted through them from one bar to the other is to reduce this concavity, or approach their middle portions nearer to the shaft, and, since they are placed diametrically opposite, also nearer to each other. At the same time the angle between the crossbars is slightly increased, the bar on the propeller shaft lagging behind that on the engine shaft.

Since it requires an infinite pull (if applied longways) to absolutely straighten a spring, it will be seen that the capacity of this dynamometer to deal with large forces is only limited by the tensile resistance of the steel, and a maximum of energy can be thus transmitted with a minimum weight of springs.

The deformation of the springs when under strain is registered by a pencil upon a paper cylinder revolving synchronously with the shaft, but at a convenient distance outside it. The pencil is moved by a system of light levers and steel bars connected with the middle of the springs. A second and fixed pencil is used to draw a datum line on the paper, and each revolution gives one diagram.

(TO BE CONTINUED.)

## CRITICAL COMPARISON BETWEEN THE TRANSMISSION OF ENERGY BY ELECTRICITY AND BY THE USUAL MECHANICAL SYSTEMS.

The December number of the *Elektrotechnische Zeitschrift* contains an article under the above title by Mr. A. Beringer, of which the following is an abstract:—

According to the distance to which energy is to be transmitted, a broad distinction can be made in the apparatus used for this purpose. For very small distances, belts, gearing, cranks, or connecting rods are used, but do not enter within the scope of the present article; for greater distances electricity, water, air, or rope gearing can be used, the distinguishing feature being that either of these agents can be applied for distances up to and exceeding 1,000 yards.

To find the basis upon which we are able to judge the efficiency of any particular system, we enter into the following consideration:—

Let the machine receiving the power be placed close to the prime mover, then the money value of a unit of mechanical energy will be the same in both machines, since no intermediate apparatus exists which would increase that value. The price which has to be paid per unit of work and time is a known and fixed sum, depending only on the kind and size of the prime mover.

But if we insert between the two machines some apparatus for the transmission of energy, the price of its unit at the receiving end will be increased, partly on account of interest on capital outlay for this apparatus, and partly on account of the loss inevitable in transmission, which loss necessitates an increased power at the generating station. The real value of a unit of work received is the sum of these items, and to find it we must know—

1. The value of a unit of work given by the prime mover.
2. The efficiency of transmission.
3. The cost of installation and maintenance.

The value of a unit of work differs with the kind of prime mover and its size.

The money value of 1 horse-power per hour is—

| | Shillings. |
|---|---|
| For small steam engines ..... | 0·3160 |
| „ medium „ ..... | 0·2190 |
| „ large „ ..... | 0·0850 |
| „ gas engines ..... | 0·2550 |
| „ water wheels and turbines ... | 0·0066 |

### 1. *Electric Transmission.*

In considering this system of transmission we must distinguish between generator, circuit, and motor. The total efficiency is the product of the efficiencies of these three items. We must also distinguish between electrical efficiency—that is, the ratio between the electromotive forces in generator and motor and mechanical efficiency, which is the ratio of work received from the motor to work put into the generator. Assuming for the present the process of transformation from mechanical to electrical energy and *vice versa* to be perfect, then the mechanical and electrical efficiency will be the same.

Let $A_1$ be work put into generator,
$A_2$ work received from the motor,
S total heat developed,
E electromotive force of generator,
$e$ electromotive force of motor,
C current,
R total resistance, and
$\alpha$ a constant depending upon the units employed.

$$A_1 = \alpha E C,$$
$$A_2 = \alpha e C,$$
$$S = \alpha R C^2.$$

$$\text{Efficiency } \eta = \frac{A_2}{A_1} = \frac{e}{E}.$$

Since $A_1 = A_2 + S$, we also have

$$\eta = \frac{A_1 - S}{A_1} = \frac{E - CR}{E}.$$

The total resistance R comprises that of generator R $g$, circuit R $e$, and motor R $m$, and we find, by reference to installations in actual use,

$$\frac{R\,g}{R} = \frac{R\,m}{R} = 0{\cdot}25.$$

In the experiments of M. Marcel Deprez, in Munich, this ratio was somewhat smaller, viz., between 0·18 and 0·24.

We are thus enabled to calculate the electrical efficiency if we know the resistance and the dimensions of the circuit.

For the latter, Sir William Thomson has given a simple formula, which takes into account the combined loss due to energy wasted and interest on capital outlay.

In similar manner we find for copper leads the area $q = \frac{C}{60}$ square centimetres, or $q = \frac{C}{384}$ square inches; and for iron leads $q = \frac{C}{7}$ square centimetres, or $q = \frac{C}{45}$ square inches if the current be given in amperes.

By using these formulæ it will be found that the resistance as well as the cost is approximately the same for iron and copper, and thus it will only be necessary to consider copper leads in these calculations.

To determine the diameter of the conductor it is now only necessary to make a choice as to the current which shall be employed.

Assuming the total efficiency to be 50 per cent., and the power required at the receiving station to be 5, 10, 50, and 100 horse-power, then, with an electromotive force of 1,500 volts, we should require 5, 10, 50, and 100 amperes respectively.

An electromotive force of 1,500 volts in the generator is quite admissible, since in M. Marcel Deprez's experiments it was even higher. It varied between 2,000 and 2,400 volts.

Digitized by Google

In these four cases the diameter of a round copper-conductor would become

$$d = 0{\cdot}32\ \ 0{\cdot}46\ \ 1{\cdot}03\ \ 1{\cdot}45 \text{ centimetres, or}$$
$$d = 126\ \ 181\ \ 405\ \ 530 \text{ millimetres.}$$

The resistance in ohms per kilometre is

$$R\,e = 2{\cdot}03\ \ 1{\cdot}01\ \ 0{\cdot}20\ \ 0{\cdot}10.$$

The loss of energy per second caused through the resistance of one kilometre of single lead is in kilogrammetres

$$A\,o = 5{\cdot}17\ \ 10{\cdot}34\ \ 51{\cdot}73\ \ 103{\cdot}46.$$

If the distance between motor and generator is K kilometres, the loss in the out and home leads will be 2 K A $o$, and since $R = R\,e + R\,m + R\,g$, and $R\,m + R\,g = R\,e$, the loss due to the resistance of motor and generator will also be 2 K A $o$.

The electrical efficiency is

$$\eta 1 = 1 - \frac{4\,K\,A\,o\,g}{E\,C},$$

or, by inserting the actual values,

$$\eta 1 = 1 - 0{\cdot}027\,K.$$

Thus the electrical efficiency depends only on the distance of transmission; it is for

| | | |
|---|---|---|
| 100 | metres | $\eta 1 = 0{\cdot}99$ |
| 500 | ,, | $= 0{\cdot}98$ |
| 1,000 | ,, | $= 0{\cdot}97$ |
| 5,000 | ,, | $= 0{\cdot}86$ |
| 10,000 | ,, | $= 0{\cdot}73$ |
| 20,000 | ,, | $= 0{\cdot}46$ |

The mechanical efficiency is considerably lower, since neither in the generator nor in the motor the process of transformation is perfect, as assumed above. The latest experiments of M. Deprez show that in the generator only 87 per cent. of the mechanical energy is transformed into electrical, and that in the motor only 80·6 per cent. of the electrical energy appears as useful mechanical energy. To find the mechanical efficiency we must therefore multiply $\eta 1$ by $0{\cdot}87 \times 0{\cdot}806 = 0{\cdot}70$ and obtain for

| | | |
|---|---|---|
| 100 | metres | $\eta = 0{\cdot}69$ |
| 500 | ,, | $= 0{\cdot}68$ |
| 1,000 | ,, | $= 0{\cdot}66$ |
| 5,000 | ,, | $= 0{\cdot}60$ |
| 10,000 | ,, | $= 0{\cdot}51$ |
| 20,000 | ,, | $= 0{\cdot}32$ |

Estimating the total cost of installation when 5, 10, 50, and 100 horse-power are required at the receiving station, and allowing 14 per cent. per annum on the capital outlay for interest and depreciation, the cost of one horse-power hour actually transmitted can be found from the above figures.

TABLE I.

Cost of 1 horse-power hour in shillings if transmitted by electricity (potential 1,500 volts).

| H.P. transmitted. | Distance in Metres. | | | | | | Prime mover. |

By a similar reasoning Mr. Beringer finds the cost of the unit of energy in the case of hydraulic, pneumatic, and wire rope transmission. We need not reproduce his calculations for these systems, but give the results arrived at in the following tables:—

TABLE II.

Cost of 1 horse-power hour in shillings, with hydraulic transmission.

TABLE IV.

Cost of 1 horse-power hour in shillings with wire-rope transmission.

| H.P. transmitted. | Distance in Metres. | | | | | | Prime move. |
|---|---|---|---|---|---|---|---|
| | 100 | 500 | 1,000 | 5,000 | 10,000 | 20,000 | |
| 5 | 0·094 | 0·122 | 0·157 | 0·455 | 0·868 | 1·899 | steam |
| 10 | 0·093 | 0·115 | 0·142 | 0·375 | 0·709 | 1·593 | |
| 50 | 0·090 | 0·098 | 0·108 | 0·212 | 0·376 | 0·925 | |
| 100 | 0·019 | 0·095 | 0·102 | 0·184 | 0·319 | 0·813 | |
| 5 | 0·009 | 0·016 | 0·025 | 0·104 | 0·207 | 0·406 | water |
| 10 | 0·008 | 0·014 | 0·021 | 0·080 | 0·159 | 0·333 | |
| 50 | 0·008 | 0·009 | 0·010 | 0·032 | 0·060 | 0·134 | |
| 100 | 0·007 | 0·008 | 0·009 | 0·023 | 0·042 | 0·099 | |

From these tables the author concludes that in all cases where these four systems are equally applicable wire-rope transmission is best for distances under one kilometre (1,100 yards), and electrical transmission for longer distances. He further concludes that water power can be electrically transmitted to a distance of 12 miles without becoming more expensive than the power produced by a local steam engine.

The result is somewhat different if, instead of water power, the steam power of a large engine has to be transmitted. In this case wire-rope gearing is generally preferable to electrical transmission. But if power has to be distributed to many points—as, for instance, in a system of town supply for small workshops—transmission by wire rope becomes impossible, on account of complication, and only the three other systems can compete.

## REVIEW OF THE YEAR 1883.

(CONCLUDED FROM PAGE 211.)

ELECTRIC LIGHTING.—Continuing our sketch of the work done last year there is one point to which we may call attention, viz., to the manner in which a number of local firms have directed their attention to this kind of business. A considerable number of private installations have been carried out without the aid or the paraphernalia of huge companies, and we have no doubt this practice will be greatly extended. There are scores of firms that will undertake to put down plant for a private gas works, and we see no reason why there should not be as many firms able and willing to install the electric light on a similar scale. A good engineer requires but a slight apprenticeship to enable him to undertake the practical work of these installations satisfactorily. Among the many local firms who have carried out electric light work of this class we may mention

Messrs. HOLMES and VAUDREY, of Liverpool, as having completed installations at Eberle's Army and Navy Hotel, London; at the Conservative and Junior Conservative Clubs, Liverpool; at Eberle's Restaurant, Liverpool; at the Grand Hotel and Messrs. Willey and Co.'s show rooms, Liverpool, and at Messrs. Woodward, Grosvenor, and Co.'s carpet factory, Kidderminster, &c.

Messrs. JOHN DAVIS and SON, of Derby, have supplied the firm of Messrs. Fletcher and Co. with Weston arc lamps and a Bürgin dynamo for their fitting shop. This firm has also lighted experimentally the pit head of Messrs. Nadin and Co.'s Stanton Colliery with Maxim lamps, the current being obtained from a Siemens dynamo, and a portion of Mr. Orchard's lace mills, at Long Eaton, with incandescent lamps.

Mr. J. A. FAHIE, of Dublin, is now engaged completing an installation in the newly fitted-up offices of the *Irish Times*. This, we are told, is the first newspaper office in Ireland in which the electric light has been introduced on a large scale, and it is anticipated that the temperature in the composing room will be far more satisfactory than with gas. It passes our comprehension why the incandescent light is not generally used in composing rooms. One reason we have heard given for this is that compositors are unable to work satisfactorily except in an atmosphere and at a temperature that ordinary mortals would naturally avoid. Mr. Fahie has been calling attention to the possible service that electricity may render in connection with the numerous tramways projected in Ireland.

We may here introduce a correction in our statement relating to WILSON HARTNELL, of Leeds, in the early part of this review. Electric light plant has not been put down at Messrs. Barrant and Co.'s, as stated, because no power was available, and to the work done should be added installations for the Leeds Forge Company, Messrs. Trumble and Sons, Messrs. Reynolds and Haslegrave, and Messrs. Peel and Co.

Messrs. LAING, WHARTON, and DOWN, of Holborn-viaduct, have, amongst other works, carried out a supplementary installation of incandescent lamps for Mr. Van der Weyde, the eminent photographer, in addition to his arc lamp already installed, an arc installation for lithophotographic work; a temporary installation on board H.M.'s gunboat "Rainbow," in connection with some festivities there; several bazaar installations, including St. Peter's Church, and the old church, Lewisham. They also lighted some stands at the late Brewers' Exhibition, Agricultural Hall, including that of Messrs. S. Mason and Son, the well-known electro-platers. Early in November they lighted at very short notice (thirty hours) the Fine Arts Exhibition in Kendal, and this lighting was continued for several weeks. They have also just finished a complete installation of about eighty lamps at a gunpowder works, all possible precautions having been taken to insure complete safety. The general offices are fitted up, and the circuit extended to the managing director's house, installing thirty-five lamps there. This use of the incandescent light in works of the description named is deserving of more extended notice, and we give further details in the following paragraph:

APPLICATION OF THE ELECTRIC LIGHT TO GUNPOWDER WORKS.—An interesting installation of the electric light has been carried out by Messrs. Laing, Wharton, and Down, at the gunpowder works of Messrs. W. H. Wakefield and Co., Gatebeck, near Kendal, this being the first works of the kind to adopt this brilliant and at the same time safe mode of illumination. The works are very extensive, at least two miles in length. The dynamo is placed about the centre of the works. Very long mains were thus necessary, as each dangerous building is about 200 yards from its neighbour. Overhead bare wires were found to be the best for conveying the current. These were carried on insulators on posts or trees along the route, branch wires being taken off to each building, four to eight lamps being

Digitized by Google

necessary for each. The lamps are fitted in specially-designed watertight copper reflectors, with plate glass fronts fixed on posts outside the windows, throwing the whole of the light inside the building, and as danger from lightning had to be guarded against, each branch as it was taken off the main overhead wires was brought into a solid teak box of novel design, each wire being brought through a lead cut-out to a separate plate of brass fluted underneath, one large plate equal in area to the two top plates being under these and fluted at right angles on its upper face, its lower side being in contact with earth by means of a No. 8 copper wire and a good earth connection. The two upper plates are then separated from each other, and from the bottom plate by paper boiled in paraffin wax. From the two plates wires are then led off through other cut-outs and a switch to the lamps; thus ample protection is given, not only from the effects of lightning, but also from excess of current from the dynamo. Besides the "dangerous" houses, the saltpetre-making factory, joiners', millwrights', and other shops, and the clerks' offices are thoroughly lighted, each lamp having its own switch and cut-out. There are also several outside lights on posts about the works to light the extension system of tram lines. The lamps used are the new pattern 12-candle Swan lamps, requiring an E.M.F. of 59 volts, and taking a current of about ·67 ampere. The dynamo is a Crompton compound-wound self-regulating Bürgin, which runs almost continuously day and night at this season of the year, the average work per day being at least 20 hours, although a great part of the time only about 10 or 20 lamps are alight. The whole of the work has been carried out under the personal direction and supervision of Mr. C. J. Wharton.

The same firm has also lighted the private residence of Mr. J. W. Weston, at Endmoor, near the above works. The current is taken from the machine driven by a turbine at the works by a single overhead bare wire on posts and insulators to the house, a distance of about three-quarters of a mile, an earth return being used. The lamps are chiefly hung from the ceilings by silk covered flexible wires with Venetian glass shades, and produce a very pleasing and artistic effect. Every room in the house, together with the stables and offices, are lighted by these means, and no other form of light is now used, about 40 lamps altogether being installed.

Messrs. Woodhouse and Rawson are to be numbered among the most energetic workers in the electric light field; but, as in other cases, the year 1883 was with them to a great extent a year of preparation and organisation, although a large amount of business has been done. They describe their work according to the department—manufacturing, contracting, or supplying. In the manufacturing department they carry on the making of incandescent lamps, electric light fittings and adjuncts, such as measuring instruments, switches, lamp-holders, &c. A good deal of experimental work has been carried out in this department which has resulted in a number of patents. Among the apparatus patented may be mentioned:—(1) Holder for small incandescent lamps with variable resistance coil, (2) ammeter, (3) voltmeter, (4) safety cut-out, (5) switches, (6) lamp-holders, and primary battery, &c. They have been most successful with their incandescent lamps, which they have rapidly improved since last year. This has been done by constantly experimenting, and by purchasing those patent rights which they considered to be most essential for this purpose. It may be mentioned that the whole of their works will shortly be consolidated in the factory now being rapidly fitted up at Kensington. This factory, when complete, will be capable of turning out from 5,000 to 10,000 lamps a week. The Gaulard-Gibbs machines, as used for the experiment in the lighting up the Metropolitan Railway Company's stations, were manufactured by this firm for the National Company for the Distribution of Electricity, &c. Besides using large quantities of wire the firm has commenced covering wire, and has already covered some 30 or 40 tons. In addition to the manufacturing operations, Messrs. Woodhouse and Rawson have during the past year carried out electric light installations at Messrs. Lewis's, Liverpool, where fifty Pilsen arc lights are used, and a temporary installation for four arc lights at Messrs. Churchill Brothers, Ireland. They assisted in carrying out the installation at the Army and Navy Hotel, where 200 incandescent lights are used. They lighted Barrett's mineral water works with 60 incandescent lamps, and the Gloucester Lunatic Asylum with 70 incandescent lamps. At the Fisheries Exhibition they had 350 lamps. The steamship "Gabo" has been lighted by 100 lamps, and the "Cahors" with 135 lamps. A temporary installation was made at the Ringwood Exhibition, where six arc lamps were used. Mr. Burke's house, Gortmoor, Ireland, is being fitted up with eighty incandescent lamps.

The supply department really partakes of the nature of a wholesale and retail business in everything connected with electrical work, for not only will purchasers be supplied with Messrs. Woodhouse and Rawson's own manufactures, but with materials of other manufacturers. They have the sole agency for the electrical goods manufactured by the United Asbestos Company, the Ragosine Oil Company, and the Belfast Electrical Appliances Company. The latter company is making a speciality of carbons, which are said to have been tested satisfactorily. It is of some importance to firms dealing casually with electrical work and to amateurs to know where they can obtain all the information as well as all the odds and ends they require. As will be seen Messrs. Woodhouse and Rawson seem to have thought of these multitudinous requirements and to have directed their attention to the supply.

The Brush Midland Company, by its secretary, informs us that the lighting of the Rev. H. W. Sneyd Kynnersley's house at Ascot should have been credited to this company, the parent Brush, however, supplying the Victoria dynamo. Sellon-Volckmar accumulators are used in this installation. Besides the above a number of installations have been carried out by the Midland Brush, among which may be mentioned those at Cleethorpes with 16 arc lights; at Messrs. Blackburn and Attenborough's, Nottingham, with 3 arc lights; at Messrs. Birken Bros., Nottingham, with 10 arc lights; at Leicester the company has fitted up 14 arc lights at Messrs. Corah, Sons, and Cooper's, and 5 arc lights at the Royal Opera House. The Corporation of Nottingham has been supplied with 10 arc lights; the New Royalty Theatre at Chester with 3, and Messrs. T. and T. Paget, bankers, Leicester, with 2 arc lamps, while incandescent lighting has been carried out at Messrs. Corah, Sons, and Cooper's; at Messrs. Birken, Brothers', &c. Mr. G. Percival, of Cork, has carried out an installation of 104 Swan 20 candle-power lamps, and 4 lamps of 40 candle-power for Messrs. Ogilvie and Moore, Warren's-place, Cork. The current is supplied by a compound shunt Gramme, by Murgatroyd and Co., driven by an engine built by the Newry Foundry Company.

A part of the history of the year is the introduction of the electric light into Buckingham Palace. It will be remembered that last season the State balls and concerts were

Digitized by Google

lighted by means of Swan lamps. The work in connection with these installations has been carried out by officials of the household, with the assistance of Mr. W. H. Massey, of Twyford. The external work was of a temporary character, but the internal arrangements are permanent. We hope this year to have to chronicle the completion of the work at Windsor Castle, where preparations have long been made for the introduction of this light.

Wire Drawers and Coverers.—One of the most important items, and especially when £ s. d. is considered, in electrical work is wire. The introduction of telephony and electric lighting gave an impetus to the production of wire specially prepared for use in these directions. The firms which are most prominent in the supply of wire, or, at least, the firms known to us, may be briefly mentioned.

The Telegraph Construction and Maintenance Company, at their large works in Wharf-road, City-road, supply large quantities of covered wire, more especially that insulated with gutta percha. Messrs. Siemens also supply large quantities of such wire, as does the India Rubber and Gutta Percha Company. Each of these firms has its specialities, and all are too well known to need introduction to our readers. Then Messrs. Glover and Co., of Manchester, have supplied in increased quantities wire and cables for telegraphy, telephony, and electric lighting, both at home and abroad.

During the year Messrs. Phillips Bros. were unfortunate in having their Homerton Factory burnt down, though having a second factory at Hackney Wick, E., they were only inconvenienced by the calamity, instead of being brought to a standstill. Mr. C. Phillips, electrician, late of the Eastern Telegraph Company, has joined the firm, and great energy has been shown in adding to the factory and machinery so as to meet the demand upon them. A large portion of the work of the firm is in the supply of the foreign as well as the home trade. It is, perhaps, a feature in this factory that it is wholly lighted by incandescent lamps, the current being supplied by Bürgin machines, made by Messrs. Crompton. The light has given the greatest satisfaction. Messrs. Callender have supplied a fair quantity of wire. We noticed that some of the cables used at the Law Courts were supplied by this firm, and we understand that the cables used in the Victoria installation are also by Messrs. Callender. We must not forget Messrs. Felten and Guilleaume, whose agent, Mr. Dennis, in this country, is quite able to hold his own, and to show our manufacturers that, while they can execute orders abroad, they must meet with competition at home. The London Electric Wire Company and the Phosphor Bronze Company are increasing the output of their specialities. Indeed the latter company seems to have an immense field open in the supply of telephone wire, &c. No doubt there are other companies which are equal in all respects to those we have mentioned, but unfortunately they are unknown to us.

Miscellaneous.—Messrs. Elliott Brothers inform us that they have had a very busy and a very satisfactory year, and that the prospects of 1884 are very encouraging. What more can be required? For this Messrs. Elliott may thank —Messrs. Elliott, in that all instruments stamped with their name are recognised as good. They are not, like some firms, who, having in bygone days made a name, trade on a past reputation. In like manner may we speak of Messrs. Johnson and Phillips. Quite accidentally we were standing by when a list of "apparatus required" was put forward for a necessary signature. Looking over the list before signing the question was asked, But are not these things dear? The reply was, We can for the same money get far better goods than from—— (The dash indicates a maker of world-wide reputation.) There is no doubt that Messrs. Johnson and Phillips have acquired a name for thoroughness of work that gives the firm a reputation second to none. We have at times described and illustrated some of their work, and we hope ere long to be able, by the courtesy of the Government Telegraph Cable Department, to describe and illustrate the machinery constructed by this firm for the "Monarch." The firm has been busy during the past year, and have greatly extended their works.

The introduction of insulite during the past year for the making of batteries, &c., should not be unnoticed. These batteries have been and will be found exceedingly handy. Time, of course, is the best proof of the value of any apparatus, but so far our experience of the battery and bell combined as issued by the Insulite Company has been very satisfactory. In order to test the value of the combination for warm climates we placed a battery in a kitchen where the temperature is usually very high, and it has been in constant use for some months without a failure. The material is being used in other directions, so that we may reckon insulite as having obtained a permanent footing in electrical work.

And now our brief *resumé* of 1883—for brief it is, although it has reached through three numbers—must close. Other work has undoubtedly been done, but it is our misfortune to remain ignorant of it, and we can but trust that readers will in the future enable us to give a more faithful report of things electrical than we have been able to do either in the present or in the past. We would have our weekly report of progress as perfect as possible, and this can only be done by the unselfish aid of our readers. Many are busily occupied day by day, they have good intentions to send us news, but not being able to jot it down at the moment they think of it, the time passes and the news is not sent. Others think the news of insufficient importance and do not send it. We would ask that all news be sent whether it be thought important or not.

## THE THEORY OF DYNAMO-ELECTRIC MACHINES.

(CONTINUED FROM PAGE 176.)

### 5. *Induced Action of the Moving Wire on Itself.*

It now remains to consider the action which the current in the moving wire induces on that wire itself. For this purpose we must remember that this wire moves only as a whole, so that any two parts always keep their relative position; hence the motion in itself cannot produce any induced action.

It is therefore only the reversal of the current, *i.e.*, the change in direction which takes place twice in each revolution, that can produce any real inductive effect. This point has been treated by Maxwell* and by Joubert†, and the author agrees with their conclusions as to the principles involved, though not as to the details of the calculation.

As any portion of the coil passes under a contact spring, the reversal takes place in the following manner:—Up to a certain time the portion belongs entirely to one particular half of the rotating coil. Then follows a very short interval, during which both ends of the member are in contact with the spring, thus forming the member into a closed circuit. After this the member belongs to the other half of the rotating coil. As the circuit is thus for a short period closed, we must not assume that it enters the second half of the coil with a current exactly the same as that with which it left the first, and therefore that the reversal takes place entirely in the second half; but rather that the reversal takes place in

* *Phil. Mag.* (4) 33, p. 474, 1867. † *Comptes Rendus* 96, p. 641, 1883.

Digitized by Google

part during the interval, and is only concluded in the second half.

Each of these successive changes of direction produces a double induction. First, an induction on the portion under consideration, which we may call for brevity the "self induction:" and secondly, an induction on the other members of the rotating coil.

We will first take the part of the reversal which takes place in the interval while the circuit is closed. Any self-induction taking place in this interval may be neglected, because the circuit is for the moment closed, and does not form part of the wire for which we are determining the E.M.F. As regards induction on the other parts of the rotating coil, these lie symmetrically on either side of the member under consideration, and therefore the E.M.F. induced on the two sides must be equal. But as the positive direction differs in the halves of the rotating coil which lie on either side of the member, the E.M.F.'s induced in the two are of different signs, and will therefore cancel each other. Hence the part of the change of current which takes place in the interval produces practically no induced E.M.F. on the wires as a whole.

We pass on to that part of the change which takes place after the member under consideration has entered into the second half of the rotating coil. The self-induction produced here must be taken into account, because the member now forms part of the whole coil. The induction on the remainder of the coil is also in a different position from before. The two halves lying one on each side are no longer exactly equal; for the member has next to it on the one side a member which is closed by the contact spring, and forms no part of the coil, and on the other side a member which is in the ordinary condition. Therefore the two E.M.F.'s induced on the two sides do not cancel each other completely, but there remains on the last-mentioned side an excess of induced E.M.F. which, like that produced by self-induction, is opposed to the direction of the current.

To find this excess, we must determine the electro-dynamic potential of the member under consideration with regard to an adjacent member, the first being supposed to be traversed by the actual current, and the latter by a unit-current. Again, to find the E.M.F. due to self-induction, we must determine the electro-dynamic potential of the member on itself, assuming it to be traversed at one time by the actual current, and at another by a unit-current. The induced E.M.F. is given by the change produced in this potential by the change in the intensity of the current. We must not here take into account the whole reversal of the current, but only that part of the change which takes place after the entry of the member considered into the second half of the rotating coil. For this part no general expression can be given, depending as it does on the construction of the machine and arrangement of the contact springs. We must therefore be content to give an expression containing one indeterminate factor.

The whole E.M.F. produced by the inductive action of the moving wire on itself, which we may call $E_2$, is always proportional to the intensity of the current, which, taking the two halves together, $i = 2$. It must also be proportional to the time of revolution $v$, because this fixes the number of changes of current. Remembering that the E.M.F. is negative, we may, therefore, put

$$E_2 = -\rho i v \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where $\rho$ is the indeterminate factor.

This factor has a remarkable property, by which a special difference is produced between $E_2$ and $E_1$, as determined above. Suppose the number $n$ of members into which the whole coil is divided to be altered, the length of each member being of course altered also in the inverse ratio, what would be the result of this on the values of $E_1$ and $E_2$? In determining $E_1$ we have to deal with the potential of the fixed current, and of the magnet, on one member of the rotating coil. This potential is roughly proportional to the length of the member, or to $\frac{1}{n}$; and as the expression has also to be multiplied by $n$, we obtain for $E_1$ an expression which is entirely independent of $n$. On the other hand, in determining $E_2$ we have to deal with the potential of a member with respect to itself and to another member. Both these (except for a term in the former, which is independent of the length) are roughly proportional to the square of the length of a member, or to $\frac{1}{n^2}$; and as they have again to be multiplied by $n$, we obtain finally for $E_2$ a value which is nearly proportional to $\frac{1}{n}$.

There is, then, this difference between the magnitudes $E_1$ and $E_2$, that a change in the number $n$ of members into which the rotating coil is subdivided has very little influence on the former, but a great deal on the latter, $E_2$ diminishing nearly as $n$ increases. Hence, as $E_2$ is negative, and implies a loss of E.M.F., it is important to make the number $n$ as great as possible.

Having obtained, in (6) and (7), expressions for the actual E.M.F.'s, $E_1$ and $E_2$, in the whole coil, we have only to add them together in order to get the total E.M.F., or E; which is therefore given by

$$E = n(W' - W'')v - \rho i v \quad . \quad . \quad . \quad . \quad . \quad (8).$$

## CORRESPONDENCE.

### THE "AMPERIAN CURRENT" HYPOTHESIS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The letter of Mr. W. H. Snell, who, if I mistake not, must be my esteemed former pupil of that name, calls for some notice on my part. In the first place, it seems to throw a doubt upon the accuracy of my explanation of the action of the Gramme machine, with which explanation Mr. Snell must have been familiar for some time past. If this be one of the objects of the letter in question, I may point out that the hypothetical amperian currents to which I referred in my short article (on p. 178) may be replaced by currents *from a battery*, traversing a solenoid representing the Gramme armature, and that the theory I have put forward may be verified step by step with this apparatus. Thus—as Mr. Snell will, doubtless, perceive without any lengthy explanation—the amperian hypothesis and my theory mutually verify each other.

It may, I think, fairly be assumed from Mr. Snell's letter that he is prepared to give an explanation of the action of the Gramme machine, as well as of other magneto-electric phenomena, on the "lines of force method," and without any reference to Ampère's theory. If this be actually the case, his elucidation of the subject would be of very great interest to many besides myself; and the expediency of giving up the whole of the amperian theory—including even the experimentally-verified analogy between magnets and solenoids traversed by a current—might be seriously entertained; albeit no explanation of magnetic attraction other than that given by Ampère is, as yet, forthcoming. But if Mr. Snell be not prepared to offer such explanation, then the proposal on his part to give up the theory which enables us clearly to account for observed phenomena on the basis of the observed analogy between magnets and solenoids appears to me as gratuitous and unacceptable as the celebrated proposal which—according to a song which was very popular years ago—was once made by an individual of the name of Aaron to another of the name of Moses.

I am not certain as to what may be the instances of apparent or actual discrepancy to which Mr. Snell refers; and I would invite him to bring them forward for the consideration of your readers. Mr. Snell is not likely to be led into error by the statement in the text books that "opposite poles attract and similar poles repel;" for he is well aware that the repulsion of opposite and the attraction of similar poles is, in the ordinary experimental investiga-

Digitized by Google

tion of electro-magnetism, as frequent as the converse phenomenon. And, in connection with this fact, a question very pertinent to the subject under discussion occurs to me. How is the student to predicate whether the north-seeking pole of a magnet will be attracted or repelled by the north-seeking pole of a solenoid or coil, and how he is to account for such attraction or repulsion, without reference to the fundamental law of electro-dynamics—the *invariable* attraction between currents in the same direction and repulsion between currents in opposite directions—which is involved in the amperian theory?

In regard to those portions of the theory in question which are not supported by—and, indeed, are opposed to—experimental evidence, Mr. Snell should be well aware that my teaching has been opposed to them. The closed circular currents of Ampère would, if we conceive them to be *straightened out*, undoubtedly exhibit magnetic polarity; and it logically follows, therefore, that such currents afford no explanation of such polarity. But in *The Engineer* of July 3, 1868, I described and illustrated an experiment showing that the *rotation of a charge* produces magnetic polarity; and in the issue of the same paper, dated February 19, 1869, I showed that electrical conduction, at least in the case of electrolytes, and probably also in the case of simple conductors, must be effected by the rotation of charged molecules. Now, as was observed by Professor Ayrton in the discussion upon the very suggestive paper on "The Cause of Evident Magnetism in Iron, Steel, and other Magnetic Metals" read at the Society of Telegraph Engineers and Electricians:—"Professor Hughes's experiments are certainly very novel and most interesting, but they may be explained in accordance with the older theories of magnetism. One of Professor Hughes's objections to Ampère's theory of magnetism is that we have no knowledge of any elementary electric currents continually flowing without any expenditure of energy. But we all, I presume, admit that the molecules of any body are in a state of rapid vibration and possibly of rotation; consequently, if they possess static charges of electricity, the rotations of the molecules will cause these charges to act like currents, and without any expenditure of energy." Such has been my view and my teaching for the last sixteen years, and it appears to me that if Hughes's molecular magnets be unsymmetrically charged rotating molecules, the phenomena he has brought forward do not involve the overthrow of Ampère's theory as a substantially valid explanation of magnetic, electro-magnetic, and magneto-electric phenomena.—Yours, &c.,

DESMOND G. FITZGERALD.

## SECONDARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The letter under this heading from the Wolverhampton Electric Light, Storage, and Engineering Company would appear to intimate that the Planté secondary battery—and, consequently, the Elwell-Parker battery—will remain in constant action for "about *twenty-three years*" without any of the plates wearing out or becoming useless. I am not certain that the company *meant* to make such a statement; but the impression which the general public would obtain from reading their letter would be to that effect. My own experience of the Planté battery, and also with similar cells "formed" by means of the corrosive action upon the lead of nitric acid, acetic acid, mixtures of sulphuric acid with sulphate of ammonia, &c., is that the duration of the anode elements—when the cells are kept in constant use and are charged from a dynamo machine—is to be measured by months instead of years. Several of the readers of *The Electrician* may rember that in November, 1881, *i.e.*, at a date somewhat anterior to that of the "great discovery" mentioned by the Company (that of the effect of nitric acid in corroding lead plates), I showed at my house some experiments with secondary batteries, including one or two constructed with plates corroded by means of nitric acid. They may remember also that the experiments with the latter were not considered very satisfactory, even at that period—far better results being obtained with electrodes "formed" by dissolving out one of the components of a lead alloy. Since that time, aided by a staff of skilled electricians, I have experimented almost continuously with a view to the construction of a permanent anode. But, although these endeavours have met with a very fair amount of success, I should be disinclined to guarantee the life of my "indestructible anodes" for so long a period as twenty-three years. I imagine, moreover, that M. Gaston Planté himself would be as surprised as any one else could be to hear that his cells would last so long in use; for, in his *Recherches sur l'Electricité*, published in 1879, he observes that "La lame positive, si elle est mince, finit par être transformée presque entièrement, avec le temps, en peroxyde de plomb à texture cristalline."—Yours, &c.,

DESMOND G. FITZGERALD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your impression of this date appears a letter from the Wolverhampton Electric Light, Storage, and Engineering Company with reference to what they call the Elwell-Parker secondary battery, which is, as they truly observe, simply a Planté battery with its surfaces roughened by a chemical process (generally by the use of nitric acid).

I think it right to point out that the employment of such plates is not the invention either of the Wolverhampton Company, of Messrs. Elwell and Parker, or of M. Gaston Planté, although perhaps patented by one or all; for it is included in the specification of Mr. John S. Sellon's patent of the 10th September, 1881, nearly twelve months before its first mention by M. Planté. This patent is the property of the Electrical Power Storage Company (Limited).—Yours, &c.,

T. M. COLLET, General Manager.

Electrical Power Storage Company (Limited), 4, Great Winchester-street, London, E.C., 11th January, 1884.

## FUSING CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Without entering upon the question of Joule's law, the truth of which is not likely to be disturbed, I may say that the point touched on at page 124 of your issue of Dec. 22nd, 1883, dealing with the effect the length of a conductor may have upon the current required to fuse it, is one not merely of scientific interest but of great practical importance. Of what use would it be to assign dimensions of cross-section alone to a safety plug, if that plug will sometimes fuse at 38·74 amperes, and sometimes at 87·35 amperes, according to other circumstances? I encountered this phenomenon in making experiments with albo-foil, and was at first rather puzzled by it. Wishing to see the rule expressed mathematically I sent some of my results to Mr. Thomas Blakesley, who has furnished me with a very useful formulæ applicable within the limits dealt with. The explanation in general terms appears to be the following:—Suppose that two equal similar and similarly situated wires of the same material, one carrying currents of equal amounts, and that these currents are just below the value for fusing the wires. If, now, a mass of colder metal is brought into the neighbourhood of one of these wires, its temperature is thereby lowered, and the balance of current wanting to bring this wire to fusing temperature will obviously be greater than that for the wire which is not in the neighbourhood of such a chilling mass. That is to say, the fusing current of the wire in the neighbourhood of the chilling mass is greater than the fusing current of the same wire when remote from such influence. Now, in the case of fusible plugs, whether of albo-foil or of lead, it is necessary to hold the ends of the plugs in metallic jaws of some sort, of which the mass is always enormous compared to the plug itself. These masses of metal conduct heat rapidly away from the foil or wire in contact with them, but the longer the foil is the less influence they have upon its middle point, so that the longer the foil the less will the fusing current be, other things being the same.

Digitized by Google

If the length is indefinitely increased the influence of its variation would disappear. This is also in accordance with the facts in the experiments you have quoted, in which you will observe that 10mm. of length between 90 and 100mm. make a difference of only 0·64 ampere in the fusing current, whereas between 30 and 40mm., the same difference of 10mm., causes one of 6·79 amperes in the fusing current.

The recognition of this effect has caused me to arrange all my fuses of uniform length, and obtain the higher melting value of current either by increasing the width or by building one on the other, carefully insulating it from its neighbours.

Another peculiarity I have noticed is that lead wire nearly always fuses some distance on one side of the middle, whereas albo-foil, when protected by mica, as in my fuses, invariably gives way in the centre.—Yours, &c.,

Westminster, S.W. KILLINGWORTH HEDGES.

## THE GRAMME MACHINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The correspondence in your valued paper between Mr. de Vane and Mr. FitzGerald has interested me very much, and induces me to ask your opinion, or that of your readers, on the plausibility of the following explanation of the causes which generate the current in a Gramme machine:—

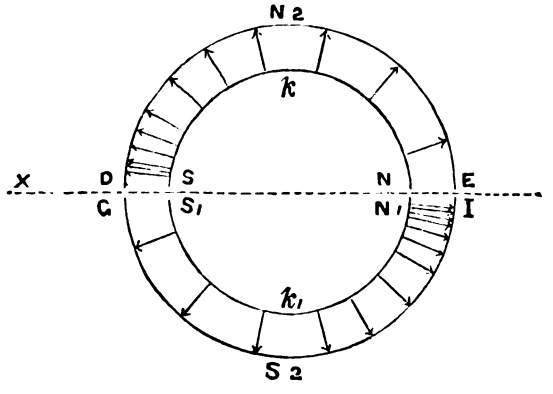
The chief thing to be considered is the direction, and the relative density of the lines of force in the magnetic field of such a machine *whilst running*.

By density I mean the relative quantity of the lines of force in spaces of same magnitude, this density being the measure of the intensity of the magnetic field.

Dynamos in general are constructed with large pole pieces, encircling the ring armature almost completely.

The current generated *in* the coils of the armature reacts *on* the core, and divides it into two equal halves, each part constituting a semi-circular electro-magnet.

Those two electros abut with similar poles, north to north, and south to south, on the same diametrical line (X Y) on which the brushes touch the collector.



The annexed diagram illustrates this. S K N $N_1$ $K_1$ $S_1$ represents the core of the armature, D $N_2$ and G $S_2$ I are the pole pieces of the field magnets. Supposing the former to be north and the latter south, then the direction of the lines of force is *towards* the centre at I, and away from the centre at D, as shown by the little arrows in the magnetic field, but besides there is a constant diminution of density of these lines from D to E and from I to G. This decrease of density is, of course, necessary for the generation of a current. The relative intensities of the magnetisms in the field magnets and in the magnetised core are of great influence on the lines of force and their direction in the field. For, if the field magnets are very strong, they invert the magnetism of the core at E and G.

If the field magnets are too weak the contrary results, the magnetism of the core inverting the magnetism of the pole pieces also at E and G.

Therefore I should think that the field magnets should be just strong enough to neutralise the core magnetism on the median line X Y at E and G. In that case the lines of force are reduced to *nil* in those points, and under these circumstances the current is generated by the motion of a conductor in a field of force of constantly decreasing intensity from its minimum to nothing.—Yours, &c.,

December 28th, 1883. TUBANTICUS.

## SMALL DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should consider it a great favour if any of your readers would give me a diagram of the Edison winding and connections of armature in one of the 25-light machines, as I wish to construct a small model of one with an armature 4in. by 3in.

I may add I have Professor S. P. Thompson's lectures, but I am not able to understand the diagram in the lecture.—Yours, &c., A. WILKINSON.

Bolton.

## RUNNING TWO DYNAMOS TOGETHER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: May I ask you or one of the readers of your valuable paper to inform me how it is that two dynamos cannot (apparently) be run together on one circuit of lamps when driven by an engine with power enough to drive both machines? I have two such small machines, which together will light fourteen 10 candle-power Swan lamps when the leads from each are separate; when, however, the machines are coupled up together, and two instead of four wires led to the lamps, I find that only one machine seems to do work. Doubtless, the explanation is a simple one, but I am not learned enough to understand it, and cannot see why the result should not be the same as with two voltaic batteries.—Yours, &c.,

A CONSTANT READER.

## DEFECTIVE DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am much obliged to your correspondents for their suggestions on the above subject.

As I cannot for want of room get any more wire on to the present F.M., I propose to place a second F.M. with a long fine coil on the upper side of the machine, bolting its poles to the present pole pieces, and connecting up the coil as a continuation of the present coil B with due care as to polarity. Does this meet with your approval?—Yours, &c.,

Wellow. R. W. OLDHAM.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I find I made a mistake in my last letter. The armature for a series machine of the size I described should be wound with ¾lb. of No. 18. I have tried No. 20, but find the machine will not work so well. When the field-magnet is wound with 5lb. No. 16 (1 ohm), and connected as a shunt on the armature, the machine will light two 9-volt 5-candle lamps, in multiple arc, at about 1,800 revolutions a minute. When the magnet is joined in series with the armature the machine will only do for small lamps of 1 or 2 candle-power, arranged in multiple arc, unless run at a very high speed.—Yours, &c., W. M. H.

Claremont House, Lee.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There being but one horseshoe, or two magnets, instead of two horseshoes, or four magnets, as I had thought, my supposition would require 5,000 ampere turns altogether. But the change doubles the calculated discrepancy.

Your correspondent does not give the sectional area of his field magnet core on which the total number of lines of force that can be produced depends.

The third equation of my letter depends on the principle that the change of the number of lines of force enclosed by

PRESS LIBRARY OF THE UNIVERSITY OF CALIFORNIA.
Digitized by Google

a circuit per unit of time is numerically equal to the E.M.F. developed, everything being in C.G.S. measure.

It is little use going into further calculation, as so many of the data are hypothetical. It is clear that an immense increase is required both of the magnet and armature coils, but especially of the latter.—Yours, &c. R. H. M. B.

## THE SOCIETY OF TELEGRAPH ENGINEERS AND OF ELECTRICIANS.

The first meeting of this society for the present session took place on Thursday, 10th inst., when the new president, Prof. W. G. Adams, F.R.S., delivered his inaugural address. The retiring president, Mr. Willoughby Smith, before giving place to Professor Adams, handed a cheque for £10 to Mr. Munro, the winner of the bonus awarded for that gentleman's paper on microphones read before the society last session. Mr. Smith also announced among the donations to the library an album of documents and mementos presented by Mr. Fahie relating to Mr. Davy's discoveries in electrical telegraphy, an account of which was recently published in *The Electrician*. The thanks of the society were awarded to Mr. Fahie for this gift, and it was stated that the council had under consideration how to deal with Mr. Davy's claims, the result of which would be announced in due time.

Professor W. G. Adams, F.R.S., in opening his address, referred with admiration to the labours of the several distinguished electricians of the last century, especially naming Franklin and Cavendish. The latter, he considered, was far ahead of his times, having formed some clear and correct ideas of the nature of potential and of electrical capacity. His calculations also in reference to relative resistances of bodies agreed in a very remarkable way with the results obtained by modern investigators. Although he had only pith balls for electrometer he was able to compare the electrical capacity of many bodies, and to obtain data which were almost identical with those of Maxwell in recent years. Whilst Cavendish was working in England Coulomb was equally active in France, inventing and using the torsion balance with which his name is identified. After this there ensued a lull, during which, however, the science of chemistry made great progress, until its combination with electrical science resulted in the discoveries of Volta at the end of the century. The further revelations of Oersted and Ampère in electro-magnetism crowded on each other until the time of Faraday, who inaugurated a new era in this field of electrical science. One of the most important discoveries of Faraday was that all electricity requires *time* for its development, a fact which Helmholtz and Thomson had subsequently confirmed. The science of energy had also been greatly helped forward by these discoverers, more especially by the more accurate instruments of measurement which they had introduced. Exactness of measurement had, indeed, been the prime mover in the enormous strides which science had made in the last quarter of a century. The methods of Wheatstone, Thomson, and Siemens were then referred to, and it was noted that at the very time Joule was formulating the science of energy that great man, Sir W. Siemens, who had just been removed from us, was applying the principle in this country to electric metallurgy and motive power. The several means of generating power, by hot air, by gas, and by steam, were next described, and their relative economical value estimated. Its conversion into electrical energy was illustrated chiefly by examples of measurements obtained at the Crystal Palace exhibition. The concluding portion of Prof. Adams's paper was occupied with some particulars concerning the methods pursued and the measurements arrived at on that occasion by himself and others who had the matter in hand. The Bürgin machine showed an electrical efficiency of 87·59 per cent. The Edison gave even better results, being as high as 93 per cent., whilst the improvements of Hopkinson had, it was said, since raised the electrical efficiency to 94 and its commercial efficiency to 88 per cent., the highest yet attained. With regard to lamps, it would seem that the efficiency of the incandescent kind very much increased with the amount of current flowing—a Swan lamp attaining an efficiency of 600 candles per horse-power when worked at its utmost limit.

At the conclusion of the president's address Prof. Ayrton rose to propose the customary vote of thanks, which he did at unusual length, and with much more of criticism than is usual on such occasions. His remarks, however, evoked no reply, and the proceedings terminated.

## ELECTRIC LAUNCHES.*

BY A. RECKENZAUN.

It is not my intention to treat this subject from a shipwright's point of view, and the title of this paper is supposed to indicate a mode of propelling boats by means of electrical energy, and it is to this motive power that I shall have the honour of drawing your attention. The primary object of a launch, in the modern sense of the word, lies in the conveyance of passengers on rivers and lakes, less for the transport of heavy goods; therefore it may not be out of place to consider the conveniences arising from the employment of a motive power which promises to become valuable as time and experience advance. In a recent paper before the British Association at Southport, I have referred to numerous experiments made with electric launches; now it is proposed to treat the subject in a wider sense, touching upon the points of convenience in the first place; secondly, upon the cost and method of producing the current of electricity; and, thirdly, upon the construction and efficiency of the propelling power and its accessories. Whether it is for business, pleasure, or war purposes, a launch should be in readiness at all times, without requiring much preparation or attention; the distances to be traversed are seldom very great, fifty to sixty miles are the average. Nearly the whole space of a launch should be be available for the accommodation of passengers, and this is the case with an electrically-propelled launch. We have it on good authority that an electric launch will accommodate nearly double the number of passengers that a steam launch of the same dimensions would; therefore, for any given accommodation, we should require a much smaller vessel, demanding less power to propel it at a given rate of speed, costing less, and affording easier management. A further convenience arising from electromotive power is the absence of combustibles, and the absence of the products of combustion—matters of great importance; and for the milder seasons, when inland navigation is principally enjoyed, the absence of heat, smell, and noise; and finally, the dispensing with one attendant on board, whose wages in most cases amount to as much or more than the cost of fuel, neglecting the inconvenience of carrying an additional individual. I do not know whether the cost of motive power is a serious consideration with proprietors of launches, but it is evident that if there be a choice between two methods of equal qualities, the most economical method will gain favour. The motive power on the electric launch is the electric current; we must decide upon the mode of procuring the current. The mode which first suggested itself to Professor Jacobi, in the year 1838, was the primary battery, or the purely chemical process of generating electricity.

Jacobi employed, in the first instance, a Daniell battery, and in later experiments with his boat on the river Neva, a Grove battery. The Daniell battery consisted of 320 cells containing plates of copper and zinc. The speed attained by the boat with this battery did not reach one mile and a quarter per hour; when 64 Grove cells were substituted, the speed came to two and a quarter miles per hour. The boat was 28ft. long, 7½ beam, and 3ft. deep. The electro-motor was invented by Professor Jacobi; it virtually consisted of two discs, one of which was stationary, and carried a number of electro-magnets, and the other disc was provided with pieces of iron serving as armatures to the pole pieces of the electro-magnets, and which were attracted whilst the electric current was alternately conveyed through the bobbins by means of a commutator, producing continuous rotation. We are not informed as to the length of time the batteries were enabled to supply the motor with sufficient current, but we may infer, from the surface of the acting materials in the battery, that the run was rather short. The power of the motor was evidently very small, judging by the limited speed obtained, but the originality of Jacobi deserves comment, and for this, as well as for numerous other researches, his name will be remembered at all times. It may not be generally known that an electric launch was tried for experimental purposes, on the lake at Penllegaer, near Swansea. Mr. Robert Hunt, in the discussion of his paper on electro-magnetism before the Institution of Civil Engineers in 1858, mentioned that he carried on an extended series of experiments at Falmouth, and at the instigation of Benkhausen, Russian Consul-General, he communicated with Jacobi upon the subject. In the year 1848, at a meeting of the British Association at Swansea, Mr. Hunt was applied to by some gentlemen connected with the copper trade of that part, to make some experiments on the electrical propulsion of vessels. They stated that, although electricity might cost thirty times as much as the power obtained from coal, it would, nevertheless, be sufficiently economical to induce its employment for the auxiliary screw ships employed in the copper trade with South America.

The boat, at Swansea, was partly made under Mr. Grove's

* Paper read at the Society of Arts on Wednesday, Jan. 16, 1884.

Digitized by Google

directions, and the engine was worked on the principle of the old toys of Ritchie, which consisted of six radiating poles, projecting from a spindle, and rotating between a large electro-magnet. Three persons travelled in Hunt's boat at the rate of three miles per hour, eight large Grove cells were employed, but the expense put it out of question as a practical application. Had the Gramme or Siemens machine existed at that time, no doubt the subject would have been further advanced, for it was not merely the cost of the battery which stood in the way, but the inefficient motor, which returned only a small fraction of the power furnished by the zinc. Professor Silvanus Thompson informs us that an electric boat was constructed by Mr. G. E. Dering, in the year 1856, at Messrs. Searle's yard on the River Thames; it was worked by a motor, in which rotation was effected by magnets arranged within coils, like galvanometer needles, and acted on successively by currents from a battery. From a recent number of *Annales de l'Electricité*, we learn that Count de Mollins experimented on the lake in the Bois de Boulogne, in the year 1866, with an iron flat-bottomed boat, carrying twelve persons. Twenty Bunsen cells furnished the current to a motor on Froment's principle turning a pair of paddle wheels. In all these reports there is a lack of data. We are interested to know what power the motors developed, the time and speed, as well as dimensions and weights.

Until Trouvé's trip on the Seine, in 1881, and the launch of the "Electricity" on the Thames, in 1882, very little was known concerning the history of electric navigation. M. Trouvé originally employed Planté's secondary battery, but afterwards reverted to a bichromate battery of his own invention. In all the primary batteries hitherto applied with advantage, zinc has been used as the acting material. Where much power is required, the consumption of zinc amounts to a formidable item; it costs, in quantity, about 3d. per pound, and in a well-arranged battery a definite quantity of zinc is transformed. The final effect of this transformation manifests itself in electrical energy, amounting to about 746 watts, or one electrical horse-power for every two pounds of this metal consumed per hour. The cost of the exciting fluid varies, however, considerably; it may be a solution of salts, or it may be diluted or other acid. Considering the zinc by itself, the expense for five electrical or four mechanical horse-power through an efficient motor in a small launch would be 2s. 6d. per hour. Many persons would willingly sacrifice 2s. 6d. per hour for the convenience, but a great item connected with the employment of zinc batteries is in the exciting fluid, and the trouble of preparing the zinc plates frequently. The process of cleaning, amalgamating, and re-filling is so tedious that the use of the primary batteries for locomotive purposes is extremely limited. To re-charge a Bunsen, Grove, or bichromate battery, capable of giving six or seven hours' work, at the rate of five electrical horse-power, would involve a good day's work for one man; no doubt he would consider himself entitled to a full day's wages, with the best appliances to assist him in the operation.

Several improved primary batteries have recently been brought out, which promise economical results. If the residual compound of zinc can be utilised, and sold at a good price, then the cost of such motive-power may be reduced in proportion to the value of those by-products. For the purpose of comparison, let us now employ the man who would otherwise clean and prepare the primary cells at engine-driving. We let him attend to a 6 horse-power steam engine, boiler, and dynamo machine for charging 50 accumulators, each of a capacity of 370 ampere hours, or one horse-power hour. The consumption of fuel will probably amount to 40lb. per hour, which, at the rate of 18s. a ton, will give an expenditure of nearly 4d. per hour. The energy derived from coal in the accumulator costs, in the case of a supply of 5 electrical horse-power for 7 hours, 2s. 9d.; the energy derived from the zinc in a primary battery, supplying 5 electrical horse-power for 7 hours, would cost 17s. 3d. It is hardly probable that any one would lay down a complete plant, consisting of a steam or gas engine and dynamo, for the sole purpose of charging the boat cells, unless such a boat were in almost daily use, or unless several boats were to be supplied with electrical power from one station. In order that electric launches may prove useful, it will be desirable that charging stations should be established, and on many of the British and Irish rivers and lakes there is abundance of motive power in the shape of steam or gas engines, or even waterwheels. A system of hiring accumulators ready for use may, perhaps, best satisfy the conditions imposed in the case of pleasure launches. It is difficult to compile comparative tables showing the relative expenses for running steam launches, electric launches with secondary batteries, and electric launches with primary zinc batteries; but I have roughly calculated that, for a launch having accommodation for a definite number of passengers, the total costs are as 1, 2·5, and 12 respectively, steam being lowest and zinc batteries highest. The accumulators are in this case charged by a small high-pressure steam-engine, and a very large margin for depreciation and interest on plant is added. The launch taken for this comparison must run during 2,000 hours in the year, and be principally employed in a regular passenger service, police and harbour duties, postal service on the lakes and rivers of foreign countries, and the like.

(TO BE CONTINUED.)

## OVERHEAD WIRES.

### Deputation to Sir Charles Dilke.

On Friday week a deputation from several large owners of property had an interview with Sir Charles Dilke at the Local Government Board with a view to having overhead wires placed under some sort of regulation. The deputation consisted of Mr. Baily, representing the Duke of Portland's estate; Mr. Beachcroft, Christ's Hospital; Mr. Wainwright, St. Thomas's; Mr. Owen Roberts, the Clothworkers' Company; Mr. Bourne, the Bedford estate; Mr. Warren, Smith's Charity, and others; Mr. Beck, the Ironmongers' Company; Mr. Hadgate, Holland Park Estate; and Mr. Cobb, Pollen Estate, and others, and the representative of the Sutton estate.

Mr. Beachcroft, in introducing the subject, said that owing to unforeseen circumstances Mr. Janson, who had acted as the chairman of several meetings which had taken place at the Law Institution on overhead wires, had not been able to be present to lay a statement of the case before him on the subject, and in his absence he (the speaker) had been requested to do so. The deputation were aware that in the month of July last a deputation from fifteen or sixteen metropolitan vestries attended at that office and urged upon the president the desirability of overhead wires being placed under some sort of control and regulation. They were aware that at that deputation the president stated that in the opinion of the legal advisers of the Government, and also in his own opinion, the responsibility for the control of all telegraph and telephone wires lay with the local authorities, and that the enactment already in force was sufficient protection.

Sir Charles Dilke: That is not an accurate report of what I stated.

Mr. Beachcroft: You are so reported.

Sir Charles Dilke said there was a correction of what publicly appeared. There were one or two papers in which he was more fully reported, and that was not an accurate summary of what he had said. That statement really went too far. He alluded in detail to the Wandsworth case, which was then undecided, and which was not finally decided yet. He thought it better not to let the statement pass without correction; it was as a fact incorrect.

Mr. Beachcroft said he referred to the report to show that a deputation did wait upon the president on the subject, and that generally speaking the reply communicated to them was to the effect that there were powers in the local authorities, and that those local authorities had better take a test case as to whether those powers were sufficient. The present deputation occupied a different position. They represented owners and important owners of property in the metropolis. He might first refer to the names of those who were present. They had representatives of the Duke of Portland's estate, the Duke of Belford's estate, Christ's Hospital, St. Thomas's Hospital, the Clothworkers' Company, the Ironmongers' Company, the Sutton estate, the Holland Park estate, the Pollen estate, Smith's Charity, and others. There were a great many others who formed the meeting at the Law Institution, but those were the names of the gentlemen who attended there that day. What was the position of owners in London with reference to that most important question? Looking to the Telegraph Acts, or more properly the Post Office Acts, the authorised companies were empowered by Act of Parliament to carry wires over, under, and all along the streets of the City of London; in other words the Postmaster-General had the power of carrying wires over streets or under streets, and over houses adjoining, or near to, the public streets. That was the position so far as the authorised companies were concerned. Now, if the question was confined to the case of the authorised companies or of the wires of the Postmaster-General they should not have had occasion to be there that day. But the difficulty which had arisen had arisen with regard to the wires—the unauthorised wires—belonging to private individuals. Those wires, within the last few years, had been increasing to an enormous extent. Only ten years ago the number of wires of private individuals and companies which paid rent to the Postmaster-General was 5,178. During the last ten years, he had very little hesitation in saying that the mileage must have increased—how manifold he was unable to say, but to a very enormous extent. And supposing the ratio of increase was to resemble the increase of the population of London, they might very well have between 50 and 100 miles of wire added every year. Now, as regarded private wires, they felt that there was the very strongest possible objections, and he would venture to state what the objections were. First of all, in their opinion private wires very materially affected the value of their property. A wire was placed over a street in front of their houses, and they had no means whatever of controlling that wire. They certainly suffered from that sort of depreciation.

Sir Charles Dilke: You have power if they place the wire over the property.

Mr. Beachcroft replied that that was so, but that he was speaking of a wire being placed over a street.

Sir Charles Dilke understood him to say over the houses.

Mr. Beachcroft said their first objection was the depreciation of the value of property owing to wires which were placed along streets facing their property. That was an objection, and as regards it they had no power. Then in the second place there was no means adopted of testing the fitness of wires that existed—no public means of testing the fitness. There were wires and they did not know whether they were good or not, but they knew that a wire had a certain life, as everything else had, and the life of the wire was from five to six or seven years, and at the end of that time

Digitized by Google

it would die a natural death. Then there were no means of registration of any sort, kind, or description, and there was no control whatever over those unauthorised wires. Then the third point was the danger which they, as owners of property, suffered from, namely—

Sir CHARLES DILKE said Mr. Beachcroft had omitted a very important question—he did not know whether he was coming to it later on, namely, as to their right of preventing the wires being put up.

Mr. BEACHCROFT stated that he would come to that. The fourth objection was that there was a danger in their opinion of adverse rights being acquired, either by reason of lessees, or tenants, or occupiers giving to any of the companies or private individuals leave to carry their wires over their premises. There was a danger of their acquiring an adverse interest—he could hardly use the term easement—but there was a danger of an adverse interest being acquired. Then there was another objection. The owners of those unauthorised wires were not known individuals. They did not know who they were. If they wanted to remove a wire which passed over their house they could not ascertain to whom the wire belonged.

Sir CHARLES DILKE: You mean in cases where they put up wires without your consent.

Mr. BEACHCROFT said without their knowledge that was frequently done. Those companies did not do their work as honest people did during the day time, but they chose the midnight hour when most respectable people were in bed, when they did not walk about London with their eyes open, and there harm arose. Then the fifth and tangible objection was that there were a very great number of wires throughout London which had become abandoned. A gentleman takes a house, and he is a business gentleman, and he wishes free communication between his private house and his business house, and he arranges for a wire, and he puts it up over his neighbour's house, and ultimately obtains the communication which he desires. He afterwards sells his house, and the wire in the ordinary course becomes an abandoned wire. Those were some of the objections—he did not know all—which owners felt to the existence of those overhead wires. It might be said—and perhaps the president might say—to them, "Well, you are lawyers who come here; surely you must know as well as I do what the law is, and you ought to take it into your own hands." He would venture to state the reasons why they were unable to do that, and the difficulty in case they endeavoured to do so. Let them take the case of the wire that crosses the street. He had a case in his own house, which was his own property, at Cravenhill, where exactly in front of his house he found a wire in such a position that some day the probability was that he should be decapitated. They were wholly unable to cope with that case because he had ascertained that the street authority had given consent, or that the wire belonged to the Postmaster-General. There he had no right to complain—personally as an owner, having no voice in the matter whatever. He could not bring an injunction against the company. The wire was not over his house, and it would be difficult to prove the damage, to assess the damage—a most tangible damage—and the value of his house was much deteriorated by the fact of the wire extending for something like 100 yards at a stretch near his house. Another reason why difficulty was felt in taking the law into their own hands was the unpopularity which would accrue if they, representing the property owners in London, were suddenly to say they would have no wires over their houses. That there was a public and popular convenience in the wires was admitted—that was a fact which could not be got over. There was no doubt that the wires serve a public convenience, and if the twelve or thirteen house-property representatives were suddenly to say that they would have no more wires over their houses, they would incur an odium which they ought not to be asked to incur. Another reason why a difficulty was felt in enforcing their rights was the difficulty which had been already expressed, namely, of ascertaining who the owners of wires are. The wires had no marks on them, and from the nature of things it was impossible that they could have marks upon them. But the wires of the United Telephone Company could be distinguished from those of the Globe Company, because the one had a ball at the top of the rests, while the other had a spike. But as regards private wires, no means of ascertaining their owners exists, and therefore it was impossible to proceed against them, supposing it was wished to move for an injunction. If property owners took the law into their own hands and disconnected the wires, then the question would arise as to how they should answer for their action. Then, again, in nine cases out of ten the wires only crossed one's house, and the rest with the ball upon it was upon your neighbour's house on one side and on the other, and the question of disconnection was one which few would be able to solve, for the reason that the wire could not be easily reached. If a revolver were taken, and the wires fired at until a disconnection was effected that would be a solution; but the case was a difficult one. And then, after the wire was disconnected, the ruin might run for half a mile or a quarter of a mile, because the moment the wire was divided the whole would recoil, and damage would be done for which possibly the owners would hold you responsible for taking the law into your own hands. Then, further, there was the risk of being told that the wrong wire had been cut, as was the case with Mr. Trunnan at Wolverhampton or at Nottingham, who was fined £5 for having cut the wrong wire, thereby endangering a stack of chimneys. As these happened to belong to the Postmaster-General, he was fined £5 for doing it. Then there was also a doubt as to what view might be taken in allowing those wires to exist and continue overhead without some proper form of control, and he (the speaker) did not know any argument so strong in favour of that view of the case as the Bill which would shortly be submitted to Her Majesty's Government by the United Telephone Company—"A Bill to afford to the United Telephone Company (Limited) additional facilities for telephonic communication in the metropolis and other purposes." In another part of this Bill the Company went on to say:—"And whereas telegraph and telephone wire when properly erected and suspended, and subjected to efficient and periodical testing, can be carried overhead without danger to the public, and it is expedient with the aforesaid object that the company be empowered to carry such wires at the heights hereinafter prescribed." The Telephone Company admitted that unless a wire was carried a sufficient way overhead there would be danger to the public.

Sir C. DILKE: Unless it was periodically examined and inspected it would be so.

Mr. BEACHCROFT assented to this remark, and wished to refer to other points *en passant*. If nothing was done, and the Bill was allowed to be proceeded with, they, as owners, would certainly do their best to prevent its proceeding in the terms in which it was presented. Their rights as owners would be entirely obliterated by the Bill, and the telephone companies have the right to carry wires over their property, and (except as regarded the streets, where they had the consent of the public authorities) owners of house property would be without any form of redress. Then there was the second objection of unsightliness. No one could approach the Law Courts without being struck by the extraordinary things which crossed the streets and entirely spoiled the appearance of the Law Courts. The enormous cables which were seen there led one to think that they must be in the neighbourhood of Billingsgate, and one looked for a great ship to justify the existence of the cables, for they were cables which crossed the Strand at that point. And if any one going up the Holborn-viaduct took the trouble, they must see and be able to judge that the condition of things was now really past endurance, and they must see that something ought to be done, else they would have some terrible disaster such as happened in New York four or five years ago, as he was told by a person who was there, when pretty nearly all the wires were broken down in a stowstorm. The Postmaster-General had intimated in a correspondence between himself and the vestries that he himself, as far as that was concerned, was doing his best to mitigate the evil, and that his department was using its best endeavours to diminish the number belonging to the Government. He admitted, therefore, that the Postmaster-General was doing his duty.

Sir CHARLES DILKE explained that the Postmaster-General stated in the House of Commons that he had reduced them to a very great extent, and gave the figures, if he could remember rightly, of the number of the wires that would go underground.

Mr. BEACHCROFT agreed with Sir Charles, and said that one pipe underground would receive a very large number of wires—80 or 90—and therefore they felt more reason, as owners and individuals, for hoping that the president would do what he could to bring about some arrangement which would place the wires which were at present overhead underground. In connection with that he (the speaker) should read the resolution of the 3rd December, which was carried unanimously, and which was as follows:—"That in the opinion of this meeting the present system of carrying wires over houses, streets, and open spaces (in other words, overhead) should be discontinued as being dangerous to the public and prejudicial to the interest of owners and occupiers of property." They maintained that there must be a means by which those wires could be carried underground. There were plenty of underground pneumatic tubes, and there need not be difficulty in finding space for others; and there were some of these spaces that were not utilised. The pneumatic tubes were 4½ feet in diameter from St. Martin's-le-Grand to Euston Station, and he was told that they were not used for anything else than pneumatic despatches but might be used by the Post Office and companies. There ought, as he had said to be some means by which these wires should be carried underground instead of overhead. In Germany the system of underground wires was carried out with great success, and there were none overhead; at least he had not seen them. The second resolution was as follows:—"That inasmuch as the carrying of wires overhead (except those of the Postmaster-General or any authorised companies coming within the terms of the Telegraph Acts, 1863-69) is not subjected to any legal control, the time has arrived for asking Parliament to interfere, and to legislate on the subject." They ventured to say in that resolution that the case of overheard wires was the only one in the metropolis which did not meet with the necessary amount of control. Either the Board of Works or the Board of Trade did in some form or another exercise some control, and give the necessary protective rights, which prevented accidents in the public streets either from the projection of houses into the streets or from fences; but the question of wires seemed to be wholly ungovernable, and they could not but think that that was an oversight. Then the suggestion they made, which they had put in the form of a resolution, was "that legislation should be somewhat on the following lines:—(*a*) That no wire be carried over, along, across, or under, any building land or street in the metropolis, by any company or person, without the license in the first instance obtained of the local authority of the district within which any wire is proposed to be laid. (*b*) That a statement of all wires existing at the present time, and of their owners, be lodged with the local authorities within a given time after passing of the Act, and that owners of wires desirous of continuing their use do together with the statement lodge an application for a license. (*c*) That, failing such statement and application, or in the event of a license not being granted thereupon, the wires shall forthwith be removed by their owners, or, in default, by the local authority of the district. (*d*). That power be reserved to the local authorities to impose such conditions, on granting any license, as they may deem needful. (*e*) That no license shall be granted otherwise than during pleasure, or for a longer period than for six months."

Sir CHARLES DILKE: Don't you think that that from you own point of view is severe?

Mr. BEACHCROFT thought that the six months should be extended. The resolution further provided (*f*). That the right of owners and occupiers to prohibit the carrying of wires over, or under, their property, be affirmed and adequately protected, and that the rights of the Postmaster-General under existing Acts be saved.

Sir CHARLES DILKE: With reference to that last clause, have you any doubts as to the rights of owners?

Mr. BEACHCROFT replied that doubt was expressed in this way—that the original Telegraph Act, 1873, Clause 30, specially provided that where at any time after the passing of the Act the Company had constructed any work either along, or across, any land or building, &c., then in such case the following provisions would take effect. The upshot was that by this Act of 1873 it was specially provided that the consent given by the lessee should not prejudice the owner, or reversioner on the expiration of the tenancy.

Sir CHARLES DILKE: Yes.

Mr. BEACHCROFT said that if Parliament itself had recognised that as a fact, the converse might be the case, viz., that supposing the lessee or the occupier gave their consent without the knowledge of his landlord, then when the landlord came in at the expiration of a lease he might find himself with a wire or a post placed on his premises, which he would be unable to do away with owing to the right of user. That was his answer to the question put by the president.

Digitized by Google

Sir C. DILKE: I did not think that you meant to distinguish between the two cases. You mean where somebody has given consent.

Mr. BEACHCROFT: Yes. I hope you will treat the matter in such a way as to not only relieve the minds of the vestries, but also the owners of house property and private individuals before some catatrophe occurs.

Mr. BAILY referred to the danger of the overhead wires. On the 29th of October, in the City, a man carelessly holding a wire allowed it to fall, and it caused serious injury to a lady, as well as doing other damage. These wires were being thrown broad cast over the whole of London. He knew an instance of a scientific chemist who wished to use his roof for certain preparations of crystals and the microscope, and on going on to his roof he found that some men were setting up wires, and within the twelvemonth four of the wires had broken and come down upon that man's front doorstep. This man cut the wires, but then that was a remedy which could not always be applied without danger. Frequently there were thirty wires stretched over a house, and the tension was so great that the consequence of cutting them could not be measured; then, again, they might be interfering with the Postmaster-General's wire, or the wire of some authorised company, and that could not be legally done. In the case of the thirty wires, the company said that the expense of removing them would be very great, and they removed the thirty and made eight stronger ones, with a long sweep overhead, and this of itself was a source of great danger, for the tension was so great, when frost came they would go. The public ought not to be subjected to that. In America they had adopted a plan of graduated taxation of those wires, and the consequence was that many were coming down. On the Continent, he believed in Germany, that had driven the wire companies into a union, and compelled them to put their wires underground. If in exceptional cases the wires were allowed to go overhead, they should be under some well regulated system. In the case of disused wires, after a snowstorm great damage would be done.

Mr. OWEN ROBERTS said he understood the telephone companies to argue that to substitute underground for overhead wires would be such an expensive process that it would be practically ruinous; but if they allowed the companies to go on the expense would be very much greater in making the alteration in the future. Science ought to be told to quicken its pace with regard to the means of substituting underground wires, and he was told that by doubling the wires and adopting other measures the expense of making the alteration need not be so great, and notice ought to be given to the companies that within a measurable distance of time this substitution should take place. It might appear rather an invidious thing for owners of property to take this matter up in the interest of property; but they were really there not so much owners of property as custodians of the public interest and safety, and he did not think they should lend the user of their property in a way to hurt other people, and it was on the latter ground that he urged that something should be done in this matter.

Sir CHARLES DILKE, in reply, said: The deputation who have attended here to-day, mainly on behalf of metropolitan property owners and incidentally as representing London interests generally in this matter, have, as has been already stated in some portion of their case, gone again over the ground which had been already gone over by a deputation which directly represented the public, and which made many statements which have again been made here to-day. The deputation of the local authorities which attended here last year made a case at a time when legal proceedings were about to begin on the part of the district of Wandsworth which were likely to clear up a portion of law on this subject, which is very difficult as regards local authorities. I believe that the Wandsworth case has not entirely come to an end up to the present time, and I have also heard that either the parish of Marylebone or some parishes together, Marylebone being one of them, are now taking counsel's opinion as to the exact position of the law so far as the local authorities are concerned, and I shall see my way perhaps more clearly to stating definitely what course it will be my duty to pursue when the legal position of the local authorities has been completely cleared up. I do not think that there has been a strong case made as regards what may be called the great companies in this matter. There is, of course, the danger arising from the peculiar states of the atmosphere, such as a gale of wind or a thaw following a heavy snowstorm, where there may be an accumulation of ice upon the wires. In such cases, though there may be a danger, still up to the present there has been no disaster resulting from overhead wires in the metropolis; but the greatest danger, no doubt, is that of the gradual decay of the wires put up by private individuals or small companies that have disappeared. As regards the larger companies, the Bill of one of them has been referred to, and I have received a letter written on behalf of the United Telephone Company, of which the writer stated that I was at liberty to make any use which I thought fit. The United Telephone Company point out the very large interests which are at stake in this matter, and, referring to a Bill which they are about to introduce, they say "that in Manchester, Liverpool, and other large towns governed by a single municipality there has been no difficulty in settling reasonable regulations with regard to the run of those wires (that is overhead wires), and were London under a similar Government, the same would, I doubt not (that is, their agent says so), be possible here. Having regard, however, to the anomalous state of affairs in London, the directors have thought it both the wisest and the most straightforward course to bring the question before Parliament. You have, perhaps, seen the Bill which the company has lodged, and I trust that we shall be able to satisfy the House in due course that its provisions will give the public all possible protection, and will at the same time afford all reasonable facilities for the extension of telephonic communication." That is the view of large companies, and as regards those large companies, when those private Bills come before the House it will be the duty of this Board to express an opinion, either through my voice in the House itself, should there be a debate, or by report to the Select Committee before which the Bill may go. But there is the more dangerous case of the unowned wires—the wires which are dropping into decay, and as regards those I think there is a strong case made out both by the deputation of the vestries last year and by your deputation here to-day. I think myself that there can be no doubt that there ought to be a power in the local authority to remove wires that are not owned, and wires which sooner or later must become a source of public danger. As far as that matter goes I have certainly a distinct opinion. Now, I have said already that there is some doubt as to the legal powers of local authorities at the present time, and that I should feel my way if that doubt had been already brought to an end; but I thought it desirable to state that as regards that class of wires I have no doubt that such a power should exist. There is no doubt that the giving of such power would involve some sort of registration, or some sort of permission given to local authorities such as has been alluded to to-day, although the conditions suggested by you were, I thought, unreasonably stringent and severe. I may say that this matter, as personal allusions have been the order of the day, is one which comes home to me, inasmuch as I have two sets of wires, one over my own garden, without any permission on my part, and I have already taken the course which has been suggested of warning my servants that they should exercise a proper watch to prevent additions being made to that large set of wires. But as regards the deputation to-day, they have spoken, as the deputation of last year did, specially of the case of the metropolis, and no allusion has been made to legislation for the country generally. There would be a question of whether a sufficient difference can be shown between the metropolis and the rest of the country to justify special legislation in this matter as regards London. I have given that matter some consideration, and apart from the fact that the great provincial towns have begun with the matter themselves, and at least two or them have inserted in private Acts of Parliament provisions in regard to this matter, and that others can go on doing so from time to time—apart from that fact, there are reasons why the metropolis should be separately dealt with. In the provincial towns it is much easier to find out to whom wires belong. There is very much less risk of those unowned wires existing for any length of time. In London, from the great size of the town, there is much difficulty in finding out to whom these different wires belong, and this is a reason which may justify special action with regard to the metropolis. Now, without dealing in detail with political matters, there is a statement made in this letter which I have just read relating to the United Company, which points to the fact that subjects relating to the form of government of the metropolis are likely to come before Parliament in the course of next Session, and I think it very probable that I shall feel it my duty to say a word or two in the course of next Session with regard to this subject from the point of view of the metropolis. But, as I have said, I shall be able to speak more definitely upon that subject when the legal proceedings at present pending or being commenced by the local authorities have shown more clearly what are the rights of local authorities in the matter. There are three courses which lie before us. There is the dealing with the matter, in the first place, merely by our reports upon private Bills, by which the companies themselves may raise this question; but that would probably not be sufficient for the object which is in view, and it may therefore be necessary either that we should express our opinions—the opinions of the Government—upon any legislation which may be proposed by private members upon this subject, or it may even be necessary for us that we should ourselves promote legislation with regard to it. But as to which of those courses should be taken, I think that you will not wish that I should attempt to make any declaration to you at the present time. I merely say that this matter is continuing to have my careful attention, and that as regards one portion of the subject you have made out a case for parliamentary action.

The deputation then withdrew.

## THE ELECTRIC LIGHTING INDUSTRIES OF GLASGOW.

On Friday evening, January 11th, the first social gathering of persons connected with the electric lighting industries of Glasgow took place in the Victoria Hall, West Regent-street, when a large number of ladies and gentlemen assembled, under the chairmanship of Mr. Chas. T. Grant.

In the entrance hall were hung two of Andrew's arc lamps, while in the hall were festoons of incandescent lamps, and a fir tree behind the platform was hung with Edison and Swan incandescent lamps, in white, frosted, and coloured glass. The current was supplied by an Edison dynamo, fitted up on the premises of the Edison and Swan Electric Light Company, in West George-street, immediately behind the hall.

The visitors having sat down to the tea provided for them, letters of apology were read from Sir William Thomson and others.

Mr. GRANT then said: The first circumstance of any moment that I can make known to you is that electric lighting has taken root in Glasgow. The mustard seed has been sown. I anticipate its growth will be much quicker than is generally expected. One reason for this anticipation is to be found in the fact that the staple cannel coal supply of Lanarkshire is not at the present time worth more than eight years' purchase. This fact is I think pretty well known in certain mining circles in Glasgow, and is also shrewdly suspected by the Gas Commissioners in Ingram-street; otherwise there would be no occasion to lower the standard of quality. If this, then, be so, I consider that as a competitor in the field, and as an illuminating substitute for the gas hitherto enjoyed in Scotland, the electric light is not one day too soon in the market. Now, there can be no doubt that this new light would even at the present day have been in greater use were it not the case that many of our municipalities have large vested interests in gas, and consequently have not the inclination which disinterested representatives of the people should have to provide the citizens with the best of everything. They have, wisely or unwisely, undertaken public and private lighting within their own bounds. That power which the citizens gave them confers no right to be biased in favour of gas. However, not only do they have this bias and show it, but not long ago the larger towns of England, Ireland, and Scotland confederated together for the purpose of going a step further, by declining to take advantage of provisional orders on behalf of the people, and at the same time opposing them being granted to any joint stock company. This is a question for the citizens to remedy. There has been one great difficulty we have had to wade through, that is the disadvantages which attend all new discoveries. I refer to the errors, accidents, and mushrooms that seem inherent to the early stages of all new industries. We have suffered from these causes, but we are not to be discouraged by them, and we certainly intend to wade through them. Our gas friends have not been slow to make use of the well-known finger in this respect. Indeed, the *Journal of Gas Lighting*, more particularly its Edinburgh correspondent, seems to be in a perpetual state of excitement over this interesting and favourite theme. But, after all, our accidents will compare favourably with those which took place seventy years ago,

Digitized by Google

when tallow candles had to give way to gas. No one who has studied the early stages of gas lighting will say that the errors and accidents of electric lighting will not compare very favourably with that period. I hope there will grow out of this large gathering at least one thing, and that is an Electric Association of Scotland. Many of us will live to see the day when electric lighting is widespread, in every city and in every hamlet, and when people will look back upon this night as one of the birth-nights of this new light.

Other speakers followed, and subsequently an assembly was held.

## THE AUSTRALASIAN ELECTRIC LIGHT, POWER, AND STORAGE COMPANY (LIMITED).

The second ordinary general meeting of this Company, adjourned from the 31st ult., was held at the offices, Coleman-street, E.C., on the 14th inst., under the presidency of Mr. Randolph C. Want.

The SECRETARY (Mr. J. H. Duncan) read the notice convening the meeting.

The CHAIRMAN said he purposed reviewing the operations of the Company from its outset, but before doing so he proposed to refer to one or two matters which occurred before their origination. He also desired to state that before the report was prepared the directors conferred with several of the principal and largest shareholders as to the position and prospects of the Company, and he felt able to say that, as far as they were able to reach them, they found that they were fairly satisfied, and that the future of this Company was much nearer before them than in the case of other companies. He was quite sure that a large number of the shareholders were business men, and therefore they must have been prepared, and were reconciled to the fact that the creation and development of a business such as that of this Company must have involved considerable outlay. It had been no child's play. They had had not one little undertaking, but the undertaking of seven large and important colonies to tackle. It was thought at first when the Company was formed—there was a great deal of wild enthusiasm at the time about electric lighting—that they would be able to get to work and get rid of their patents, and accumulate money by that process, but very shortly after the formation of the Company the enthusiasm ceased, and they found that there was no chance of selling their patents. The gentlemen who had formed an intermediate Company before the inauguration of this Company, had adopted the plan of sending out an important representative to Australia, first of all to try and sell the patents, and, if not, then to endeavour to develop the business. The gentleman who was sent had been premier of one of the chief of these colonies, and the directors thought they were following very good counsel when they selected Sir Julius Vogel to go out to the colonies. That gentleman was not able to make any sale of their patents, at which, however, the directors were not surprised, seeing the change things had taken; but through his position and influence, and the reputation he had for ability, he had the power of introducing the value of their patents to all the principal colonies, and it was through Sir Julius Vogel's instrumentality that they were now working for the Governments of New South Wales, Victoria, and Queensland. He had dwelt a little specially on this, as some of the shareholders had asked him if he did not think the sum paid to Sir Julius Vogel was excessive. It did appear large to those who had hoped for quicker returns, but those cognisant of the appointment of such men, and the difficulties of the work to be undertaken, would not regard the amount paid as too large. He was prepared for some disappointment among some of the shareholders because the Company had not sooner rushed into successful results, but surely it must be known that a business such as theirs would not all at once produce profitable returns. The colonists showed on the arrival of Sir Julius Vogel they were willing to have the light not only for public use but in private establishments, but they were naturally nervous about it, as at home they saw that no progress was being made in its adoption. The price of gas in this country, however, did not admit of the introduction of electricity as readily as in those places where gas was so much dearer. They had been proving that they could give the light, and that it would work satisfactorily, and they had done that at the request of the colonists, who desired to see the light "proved" before they adopted it. He did not think the Company had done any lighting that had not been profitable, but the profits had been taken from them owing to the heavy charge made for the plant by the manufacturers. The Government of Victoria instructed them to light up one of their railways. The conditions were that the Company should put up the light, run it for some reasonable time, six months, and at the end of that period, if it continued successful and worked properly, they would take it over, and that had been done. It would, however, have been very extraordinary if they could have made a profit out of that work, seeing that it was a tentative installation; but they valued the fact that it was a thoroughly good advertisement to the Company, and they found it a great advantage to have secured the Government of Victoria as one of their customers. At Sydney the same proceeding was carried out. In each case the lights were installed, run, and paid for. The profit was exceedingly small, owing, as he had said, to the high price which was charged at the beginning for plant. Since then, however, they had made contracts at prices which would give them higher profits. He was not going to try and make them believe that they would "rush into fortunes" with the electric light—it was an enterprise which must go on steadily, but he believed that all the world was of opinion that the light was going to be a successful affair. They saw in the colonies a field for working profitably. He thought it would be very unfair to measure their prospects by the measure of their success in the past. He supposed that very few were present at that meeting who were not well aware that there were hundreds of companies who had had to go through the ordeal which those concerned in the electric light enterprise were now passing through. Gas, water, canal, cable, and other companies had had to go through some of the difficulties which the electric light companies were now meeting with, some of them for 15 years without the slightest approach to profits, but in the end the reward of patience had been reaped. A circular had been prepared giving references to the work done by the Company in the colonies, and he had hoped that it would have been in the hands of the shareholders by now. A valuable feature touched upon was the prospect of amalgamation with a company in Victoria. Before their arrival there a company having a manufacturing house, with a central station, and a good stock of plant was working there profitably and paid dividends, but this company's arrival caused a certain amount of check. It was, he said, soon found that the patents possessed by this Company were much more valuable. They had, however, not run away with that Company's work, but had had to compete with them. At the present moment negotiations were pending for an amalgamation which would throw the burden of the present expenses on the combined company.

A SHAREHOLDER: What patents have the other company?

The CHAIRMAN said he believed they chiefly worked the Maxim-Weston patents, but out in Australia people could take some liberty with patents. They had not the Brush patent, which was perfectly secure in the possession of this Company. The amalgamation was in negotiation at present, so he would not go into terms. He might, however, state that this Company was waiting to see if better terms could not be obtained. The result would be, if the amalgamation were carried out, that this Company would leave Victoria to the amalgamated company, and do all they could then in the other colonies. Up to their very latest advices, they had promises that there was a great field for them there. He might mention that if they did not amalgamate they would come to terms, under which they would work on some co-operative basis. The directors were quite aware that the shareholders must all feel that there had been a very large outlay. They had not now, however, to put up installations for exhibition, as they had them in every one of the colonies, and could point to them as admitted successes, and they now intended to take nothing else but profitable work. They spent no money now trying to show that their work was good. It was with this determination that they had resolved, instead of stopping the work of the Company and suggesting a winding up, to make a call for the purpose of continuing operations. Whatever arrangement they might make as to the amalgamation negotiation referred to, they would certainly then tackle one or two of the principal colonies, and devote all their energies to pushing the work of the Company there. The orders they had on hand and the promises of work led them to believe that there was a good field before them. They intended to reduce the expenses in every direction they possibly could. The directors were not mere "guinea pigs," for they held a considerable stake in the Company. After detailing some of the work in hand, he observed that it was only just lately that they had reached the turn of the tide. There was now a prospect of the adoption of the electric light on the steamers plying from colony to colony. The Company commenced not actually by tying themselves to any particular patent, but a very large sum had been given for the Brush patents. At the time they commenced there was no incandescent plant or dynamo connected with the Brush patent, or nothing of any value, and he was rather inclined to think that it was under the requirements which this Company had urged that the Brush Corporation had stirred themselves, and they were now possessors of one of the very best incandescent lights—the Schuckert, which was a combination of Schuckert and Brush. The Company had found favour from others in many directions. They acquired some time ago the agency of the Ferranti Company. An arc lamp had also been invented by the Fyfe-Main Company. All these patents were acquired for nothing—on the terms of buying and selling. They had also acquired an accumulator from Wolverhampton, which they believed would prove good, and they would pay nothing for it if it were not successful. There was no doubt that they paid a very large sum for their patents at starting, but no more than other companies for the same class of rights. They took no blame for having entered into the purchase, for the shareholders he maintained were parties to it; and the directors had put their money in the concern in the same way as the shareholders had done. He could vouch for the fact that the Company had received untiring attention from the Board. The uncertainty about the electric light had made the battle a hard one to fight, but he thought they could take claim—be the cost excessive or not—for having so developed the business in the colonies that the shareholders would some day reap the benefit of what had been done. They had gone through all the trials he had indicated, and they had now arrived at a point which they thought might be regarded as the turning point. He concluded by moving the adoption of the report and accounts.

Mr. J. J. CATER having seconded the motion,

A SHAREHOLDER said he thought they ought to hear Sir Julius Vogel.

The CHAIRMAN regretted that Sir Julius Vogel had been laid up for a fortnight with the gout, and was utterly unable to attend the meeting.

Mr. JACKMAN alluded to the prominent part which Sir Julius Vogel took at the outset in the purchase and the expenditure of £80,000 of the capital for that which he (the speaker) contended was utterly worthless. He inquired the present current expenses of the Company.

Mr. STEPHENS complained of the amount of the directors' fees. He argued that the only proper course for the directors to take was to wind up the Company, and he was surprised that instead of doing so they had made a call of £1 a share.

Mr. SCHULTZE asked the nature of the litigation which was pending, as to which he saw that the Company had deposited £5,000 in court.

Mr. ROBERTS inquired whether any legal opinion had been taken as to whether, if the Company were wound up, they would have any chance of recovering any of the money they had paid for the patents which appeared to be of no value.

Mr. HEZELTINE stated that there was a loss of £13,224 up to the 30th of June, and inquired what the loss was at present.

After a few observations from Colonel IMPEY as to the amount which had been paid to Sir Julius Vogel for going to the colonies,

Mr. LAMBERT asked the names of the directors at present?

The CHAIRMAN stated that there had been no change. The directors were Messrs. J. J. Cater, Latimer Clark, Philip Falk, Lieut.-General H. M. Hamilton, C.B., and himself.

Mr. LAMBERT thought the shareholders could not have a more respectable body of directors, and he thought they ought to accept the statement of those gentlemen that they had done their best. Every one was aware of the *furore* about the electric light at the beginning and the sudden smash. He wished, however, to know whether the lighting they were now doing was paying or not. Supposing the Company were wound up, would it not still be necessary for a call to be made? He should certainly prefer to pay the call to the directors in the hope of getting back some of the money he had invested rather than for it to go into the hands of a liquidator. The amount paid to Sir Julius Vogel appeared large, but unfortunately he had not been able to do what he had hoped. If Sir Julius Vogel

had been successful, he did not think the £4,000 which had been paid to him would have been criticised.

Mr. KISCH understood that the action against the Electrical Power Storage Company was for a return of part of the purchase money paid by the Company. He sympathised with three of the directors, but as to two of them he did not think they wanted sympathy, as, being vendors of the Company, they had received compensation in another way.

Mr. LESLIE thought it would have been better if the agreement with Sir Julius Vogel had been to pay him by results. He considered the directors' fees were "frightful."

Mr. ROBERT HAMMOND thought that what the shareholders desired to know was whether the new money which it was proposed to obtain by the call could be profitably employed. His connection with the electric light business in the last year or two had taught him that they had all been striving for business—that if a town had been anxious to spend £100 on the light there would be eight or ten people ready to do the work, not so much with the view of getting anything out of the £100 as to show that they were able to do the work. There was a great deal of electric lighting to be done in England—and he supposed also in the colonies—but there were people who had been willing to do the work at a loss in order to obtain it as an advertisement. He was, however, able to say, as regarded England, that that time was now at an end, and he inquired whether the same state of things prevailed in Australia.
